The Constructive Engine

Gérard Huet

INRIA
Rocquencourt, France

Introduction
The Calculus of Constructions is a higher-order formalism for writing constructive proofs in a natural deduction style, inspired from work of de Bruijn [4, 7], Girard [21] and Martin-Löf [33]. The calculus and its syntactic theory were presented in Coquand’s thesis [12], and an implementation by the author was used to mechanically verify a substantial number of proofs demonstrating the power of expression of the formalism [15]. The Calculus of Constructions is proposed as a foundation for the design of programming environments where programs are developed consistently with formal specifications [37]. This note presents in detail an implementation in CAML [18, 44] of a proof-checker for the calculus. This proof-checker proceeds by operating an abstract machine, called the constructive engine.

The description in this paper is close in spirit to the inference system described in section 10.2 of [13]. The main departure is the addition of a system of constants, allowing a form of definitional equality. The implementation shown corresponds to a simplification of version 4.9 of the system. Differences with the actual implementation are discussed below.

1 Technical Preliminaries
The constructive engine is an environment machine which manipulates λ-expressions with a rich language of types. There are several sorts of variables which may appear in the terms of the calculus. The global variables, as well as the global constants, are referenced with their name, a concrete string of ASCII characters. The environment is looked up through a hash table for fast access to the declaration information of the global. The locally bound variables are represented by their binding depth, in the manner of de Bruijn [3]. Since the constructive engine works by weaving back and forth between the environment and the currently constructed term, we need to switch representations efficiently. Also, we need to be able to compare two terms modulo β-reduction, in order to implement type equality checking. This section presents various programming techniques developed for such algorithms.

1.1 λ-calculus in the de Bruijn notation
We now recall the de Bruijn’s notation of λ-calculus. This abstract representation of λ-expressions was originally introduced by de Bruijn [3], and later extended to Automath’s

---

1 A preliminary version of this paper, describing version 4.5 of the engine, was presented as an invited lecture at CAAP88. This paper describes a simplified view of the current 4.9 implementation.
A structures by Jutting[29].

We first consider untyped \(\lambda\)-calculus. We use CAML as our specification language. The type of concrete \(\lambda\)-terms may be defined as:

\[
\text{#type concrete =}
\begin{align*}
\text{Var of string} & \quad (* x *) \\
\text{Lambda of string * concrete} & \quad (* [x]E *) \\
\text{Apply of concrete * concrete} & \quad (* (E1 E2) *)
\end{align*};
\]

Type concrete defined

\[
\begin{align*}
\text{Var} : & \ (\text{string} \rightarrow \text{concrete}) \\
\text{Lambda} : & \ (\text{string} \times \text{concrete} \rightarrow \text{concrete}) \\
\text{Apply} : & \ (\text{concrete} \times \text{concrete} \rightarrow \text{concrete})
\end{align*}
\]

Thus every variable, whether it is free or bound, is implemented by a concrete string. Such representation needs complex substitution operations, in order to guarantee the preservation of the right binding relationships. Variable renamings (called \(\alpha\)-conversion) may be necessary, and thus new names have to be coined. In order to avoid this naming problem, we define the type of abstract \(\lambda\)-terms:

\[
\text{#type lambda =}
\begin{align*}
\text{Ref of num} & \quad (* \text{variables} *) \\
\text{Abs of lambda} & \quad (* \text{lambda abstraction} *) \\
\text{App of lambda * lambda} & \quad (* \text{apply function L1 to argument L2} *)
\end{align*};
\]

Type lambda defined

\[
\begin{align*}
\text{Ref} : & \ (\text{num} \rightarrow \text{lambda}) \\
\text{Abs} : & \ (\text{lambda} \rightarrow \text{lambda}) \\
\text{App} : & \ (\text{lambda} \times \text{lambda} \rightarrow \text{lambda})
\end{align*}
\]

Now each variable occurrence is represented by its binding depth, i.e. the relative depth with respect to its binding abstraction operator. A term of type \text{lambda} containing \(n\) free variables is valid in a context of length \(n\), according to:

\[
\text{#let rec valid n = function}
\begin{align*}
\text{Ref}(m) & \rightarrow n \leq n \\
\text{Abs}(l) & \rightarrow \text{valid} \ (n+1) \ l \\
\text{App}(l1,l2) & \rightarrow \text{valid} \ n \ l1 \ \& \ \text{valid} \ n \ l2
\end{align*};
\]

Value valid = \text{<fun>} : (num \rightarrow lambda \rightarrow bool)

Thus a closed \(\lambda\)-term is one which is valid in an empty context:

\[
\text{#let closed = valid 0};
\]

Value closed = \text{<fun>} : (lambda \rightarrow bool)

We write \(\Lambda_n\) for the set of lambdas \(M\) such that \(\text{valid} \ n \ M\).

The recursion structure of algorithm valid is characteristic of computations on lambdas. The corresponding induction principle may be stated as:

\textbf{Contextual Induction Principle.} Let \(P_n\) be a property of lambdas, indexed by a natural number \(n\), and satisfying the closure conditions:

- \(P_n(M) \land P_n(N) \Rightarrow P_n(App(M,N))\)
- $P_{n+1}(M) \Rightarrow P_n(Abs(M))$
- $0 < m \leq n \Rightarrow P_n(Ref(m))$.

Then $P_n(M)$ for every $M \in \Lambda_n$. Here is an algorithm for translating a concrete term to its abstract representation, given a context of free variables:

```
#exception Unbound;;
Exception Unbound defined

#let index_of id = search 1
#where rec search n = function
#   (name::names) -> if name=id then n
#   else search (n+1) names
# | [] -> raise Unbound;;
Value index_of = <fun> : ('a -> 'a list -> num)

#let rec parse_env lvars = abstract
#where rec abstract = function
#   Var(name) -> Ref (index_of name lvars)
# | Lambda(id,conc) -> Abs(parse_env (id::lvars) conc)
# | Apply(conc1,conc2) -> App(abstract conc1,abstract conc2);;
Value parse_env = <fun> : (string list -> concrete -> lambda)

#(* parsing closed lambdas *)
#let parser = parse_env [];;
Value parser = <fun> : (concrete -> lambda)
```

The abstract representation is not convenient for the human interface, and thus we assume we have declared a grammar for concrete syntax, as follows[44]:

```
#grammar concrete =
#rule entry Lambda = parse
#   Term x -> parser(x)
#and Term = parse
#   "("; Term_list x; Term y; ")" -> Apply(x,y)
# | IDENT x -> Var(x)
# | "["; Binder x; "]"; Term y -> list_it (curry Lambda) x y
# | "("; Term x; ")" -> x
#and Term_list = parse
#   Term x -> x
# | Term_list x; Term y -> Apply(x,y)
#and Binder = parse
#   IDENT(x) -> [x]
# | IDENT(x); ","; Binder y -> x::y;;
Warning: variable(s)
curry, Apply, list_it, prefix ::, Lambda, Var, parser
```
will be dynamically bound

Calling Yacc ... .................................

Value concrete = <fun> : (string -> Parsers)

Grammar concrete for programs defined

   entry Lambda

We may now give examples in concrete syntax:

#<[[x](x [y](x y))]>;;
(Abs (App ((Ref 1),(Abs (App ((Ref 2),(Ref 1))))) ) : 
lambda

Remark that the two occurrences of \( x \) have different indexes 1 and 2, and that conversely the references (Ref 1) correspond to two distinct variables \( x \) and \( y \).

The first fundamental algorithm concerns the recomputation of global references to global variables across \( n \) levels of binding. This is computed by the algorithm \( \text{lift} \) below.

#let lift n = lift_rec 1
#where rec lift_rec k = function
#   | Ref(i) -> if i<k then Ref(i) (* bound variable : invariant *)
#       else Ref(i+n) (* free variable : relocated *)
#   | Abs(lam) -> Abs(lift_rec (k+1) lam)
#   | App(lam,lam') -> App(lift_rec k lam,lift_rec k lam');;

Value lift = <fun> : (num -> lambda -> lambda)

Now we may program substitution, as follows.

#let subst lam =
#let lift_lam n = lift n lam in subst_lam 1
#where rec subst_lam n = function
#   | Ref(k) -> if k=n then lift_lam (n-1) (* the substituted variable *)
#       if k<n then Ref(k) (* bound variables *)
#       else Ref(k-1) (* free variables *)
#   | Abs(lam') -> Abs(subst_lam (n+1) lam')
#   | App(lam1,lam2) -> App(subst_lam n lam1,subst_lam n lam2);;

Value subst = <fun> : (lambda -> lambda)

For instance, we may now program the conversion of a solvable \( \lambda \)-term to its head normal form as:

#let rec hnf = function
#   | Ref(n) -> Ref(n)
#   | Abs(lam) -> Abs(hnf lam)
#   | App(lam1,lam2) -> let lam' = hnf lam1 in match lam' with
#       | Abs(lam) -> hnf(subst lam2 lam)
#       | _ -> App(lam',lam2);;

Value hnf = <fun> : (lambda -> lambda)
These algorithms are satisfactory, as executable specifications. They are not satisfactory as efficient programs. We see two main problems with this approach. The first one is that too much unnecessary copying of structures is effected. The second one is that the operation of $\lambda$-reduction is in some sense not elementary enough: we would like to substitute occurrence by occurrence, in a maximally lazy fashion. We shall not tackle the second problem here, but will try and share as much as possible during the computation, in order to remedy the first problem. It should be noted that this very basic problem of efficient computation on $\lambda$-terms is still largely open. The sharing of combinatory dags applies only to weak reduction (where one does not reduce inside abstractions). The same is true of abstract environment machines such as the SECD, FAM or CAM machines, which furthermore compute in applicative order (innermost) as opposed to the normal order (leftmost-outermost) corresponding to the standardization theorem. Wadsworth’s method[43] does not avoid unnecessary duplications. Levy’s sharing of redex families[31] has not yet been implemented in a computationally efficient way. We do not claim that de Bruijn’s abstract representation will lead to the best implementations of $\lambda$-calculus. However, the sharing method which we shall now present leads to an acceptable behaviour for our application to the constructive engine.

1.2 Sharing morphisms

Let us forget $\lambda$-calculus for the sake of the current discussion, and consider the simpler case of terms built up from free constructors. For instance, consider the following algebra, corresponding to the abstract syntax of terms for some simplified arithmetic:

```ocaml
#type term =
  # Var of string
  # | Plus of term * term
  # | Minus of term
  # | Constant of num;;
Type term defined
  Var : (string -> term)
  | Plus : (term * term -> term)
  | Minus : (term -> term)
  | Constant : (num -> term)
```

Now let us consider a simple-minded implementation of first-order substitution over these terms, with substitutions represented as association lists:

```ocaml
#let naive_subst sig = subst_rec
#where rec subst_rec = function
  # Var(name) -> if mem_assoc name sig then assoc name sig else Var(name)
  # | Plus(t1,t2) -> Plus(subst_rec t1,subst_rec t2)
  # | Minus(t) -> Minus(subst_rec t)
  # | Constant(n) -> Constant(n);
Value naive_subst = <fun> :
    ((string * term) list -> term -> term)
```

This method is clearly computationally absurd, since a full copy of a term is effected, even when the substitution is empty. Worst, substitution will un-share terms naturally
shared on the underlying dags, such as `let M=Constant(2) in Plus(M,M)`. This may be acceptable in certain situations, for instance if we want to rewrite the two occurrences of `M` above in distinct ways. But if we think of these abstract terms as applicative structures, we want to profit of the possible sharing to represent in a shared fashion the substitution to a non-linear term such as `Plus(Var(x),Var(x))`.

One solution to this problem has been proposed long time ago by Boyer and Moore[1], and this “structure sharing” representation is now one of the classical ways to implement PROLOG. In this method, we manipulate substitution closures rather than terms, and this has some undesirable effects. For instance, we do not have a direct access to the top of the term anymore, and this access gets more and more costly the further we substitute. After a while, the whole structure may become completely inverted. For this reason, the “structure copying” implementation is still retained in many applications.

At the other end of the spectrum, we find the representations which share through congruence closure[40, 20]. These methods are fine for ground terms (not containing free variables). In the case where we manipulate mostly terms with variables, congruence closure is not really applicable, and produces more overhead than it saves.

We shall now study how to share maximally in the standard representation of terms containing free variables. We shall not try and guess possible sharing through syntactic coincidences. We only care to preserve existing sharing, and to share as much as possible of a substituted version of a term with the original version. Let us first see how to implement this idea of sharing non-substituted portions of a term. Here is a simple recursive algorithm which reports, together with its result, a boolean value indicating whether sharing has been possible or not.

```ocaml
#let subst_and_share sig = fst o subst_rec
#where rec subst_rec x = match x with
#  Var(name)    -> if mem_assoc name sig then (assoc name sig,false)
#                  else (x,true)
#  | Plus(t1,t2) -> let (t’1,b1)=subst_rec t1
#                  and (t’2,b2)=subst_rec t2
#                  in if b1&b2 then (x,true) else (Plus(t’1,t’2),false)
#  | Minus(t)   -> let (t’,b)=subst_rec t
#                  in if b then (x,true) else (Minus(t’),false)
#  | Constant(n) -> (x,true);;
Value subst_and_share = <fun> : ((string * term) list -> term -> term)
```

Again, we have a correct specification of what we exactly mean by sharing, but the program above is very costly in storage, since the computation of the sharing relationship builds on the side a duplicate of the structure in the shape of a tree of booleans. If the aim is to avoid building un-necessary structure, we must clearly avoid these explicit boolean values.

The next idea is to replace the values `(true,x)` above by an exception, signaling that sharing is possible. Let us define a sharing morphism as a term morphism, which raises a special exception `Identity` to signal that its result is identical to its argument. If `f` is such a sharing morphism, it may be applied on an argument with possible sharing with:

```
exception Identity;;
```
let share f x = try f(x) with Identity -> x;;

and now we may implement a sharing substitution with:

#let sharing_subst sig = share subst_rec
#where rec subst_rec = function
#   Var(name) -> if mem_assoc name sig then assoc name sig
#                 else raise Identity
#   | Plus(t1,t2) -> (try Plus(subst_rec t1,share subst_rec t2)
#                    with Identity -> Plus(t1,subst_rec t2))
#   | Minus(t) -> Minus(subst_rec t)
#   | Constant(n) -> raise Identity;;

Value sharing_subst = <fun> : ((string * term) list -> term -> term)

It is clear that we now have maximum sharing of the substituted term with its original pattern, without extra structure.

It may be objected however that the substitution algorithm is now cluttered with extra cases, which brings two problems: readability is questionable, and mistakes may occur in the transformation from a copying algorithm to its shared version. Note in particular that the case corresponding to an \( n \)-ary constructor splits into \( 2^n - 1 \) subcases. This objection may be overcome, by noticing that the transformation is systematic enough to be encapsulated in a macro.

More precisely, given two arguments, one which gives the signature of the constructors over which we want a sharing morphism effect, and the second which gives what happens on the others, we may write without difficulty a macro \textit{morphism} which generates the full recursion. Without giving its actual code, which would be hard to understand for readers not familiar with CAML, here is the instance of its call in our example:

#pragma let term_signature = [('Plus',2);('Minus',1)]
and replace_sig =
<:CAML<function Var(x) -> if mem_assoc x sig then assoc x sig
          else raise Identity
      | Constant(_) -> raise Identity>>;;
(* Macro-generated version of sharing_subst above *)
let sharing_subst = share #(morphism term_signature replace_sig);;

Remark 1. The macro \textit{replace_sig} above is enough to illustrate the example. It is unsatisfactory in that it assumes that the argument to the \textit{substitute} algorithm is called \textit{sig}. A more satisfactory version of the macro, parameterized in an adequate fashion, is easy to define with the mecanism of \textit{anti-quotation} of CAML[44]:

#pragma let replace_sig sig =
<:CAML<function Var(x) -> if mem_assoc x {"sig"} then assoc x {"sig"}
          else raise Identity
      | Constant(_) -> raise Identity>>;;

and now the identifier \textit{sig} is generated in its proper scope:
let subst sig = let SIG = <:CAML<sig>> (* abstract syntax of sig *)
  in share #(morphism term_signature (replace_sig SIG));;

This remark applies to the other macros explained in the next section. However, we prefer
to present the more readable “unsafe” versions.

Remark 2. The sharing mechanism we present uses ML’s exceptions. Other mech-

anisms may be thought of. For instance, if one assumes the existence of a primitive eq
which tests for physical identity, we may program a sharing substitution in the following
manner:

...  
match arg with
...  
| App(x,y) -> let x'=subst x and y'=subst y
  in if eq(x,x') and eq(y,y') then arg else App(x',y')
...

Using one mechanism or the other may be motivated by aesthetics or implementation rea-
sons (availability of primitives, efficiency). Somehow the user should not have to worry
about such low-level detail, but obviously current implementations of functional program-
ming languages lack the proper memory management primitives needed to express natu-
really this economic use of data structures.

1.3 Binding morphisms with sharing

The ideas of the previous section may be extended to algebras where certain constructors
are binding in some of their arguments. For instance, in lambda above, Abs is binding in its
argument, whereas App is not. We indicate this information with the following descriptors:

#pragma let lambda_descr = [("Abs",[true]);("App",[false;false])];

We now give the code for lifting Ref indexes over k levels of binding:

#pragma let lift_k =
  <:CAML<function Ref(i) -> if i<n then raise Identity (* bound var *)
    else Ref(i+k) (* free var is shifted *)>>;;

and the general case is macro-generated with the help of a macro binding_morphism
which generalizes the idea of sharing morphisms to binding constructors implemented
with de Bruijn indexes. Without boring the reader with the actual details of the macro
binding_morphism, let us just indicate an example of macro-expansion:

#pragma binding_morphism lambda_descr lift_k =
  <:CAML<let rec f n = function
    Abs(x1)   -> Abs(f (n+1) x1)
    | App(x2,x1) -> App(try f n x2, (try f n x1 with Identity -> x1)
                      with Identity -> x2,f n x1)
    | Ref(i)   -> if i < n then raise Identity else Ref(i+k)
    in f 1>>
Now we get the lift function as:

```ocaml
#let lift k lam = if k=0 then lam
#   else share #(binding_morphism lambda_descr lift_k) lam;;
Value lift = <fun> : (num -> lambda -> lambda)

Remark that we save exploring the term lam in the case k = 0, which we know beforehand to be an identity.

We now iterate this idea for substitution:

```ocaml
#pragma let subst_lam =
<:CAML<function Ref(k) -> if k=n then lift_lam (n-1) (* substituted var *)
   if k<n then raise Identity (* bound var *)
   else Ref(k-1)>> (* free var *);;
```

```ocaml
#let subst lam =
#   let lift_lam n = lift n lam
#   in share #(binding_morphism lambda_descr subst_lam);;
Value subst = <fun> : (lambda -> lambda -> lambda)
```

This substitution algorithm is still far from perfect. First we should recognize the special case when we substitute a closed term, since in that case no lifting is necessary. Further, we should share all instances of (lift n lam) for a given n. These ideas are implemented in the following version:

```ocaml
#pragma let subst_closed_lam =
<:CAML<function Ref(k) -> if k=n then lam (* lam is shared *)
   if k<n then raise Identity (* bound var *)
   else Ref(k-1)>> (* free var *);;
```

```ocaml
#let subst lam =
#   if closed lam
#     then share #(binding_morphism lambda_descr subst_closed_lam) lam
#     else let instances = ref [] in
#       let lift_lam n = (* local memo version *)
#         if n=0 then lam
#         else (assoc n !instances (* memo effect *)
#           ? let new_instance = lift n lam
#           in (instances:=n,new_instance)::!instances;
#           new_instance))
#       in share #(binding_morphism lambda_descr subst_lam) lam;;
Value subst = <fun> : (lambda -> lambda)
```

Further optimizations are possible. For instance, the initial pass to check whether lam is closed or not could set up the lifting code with maximum sharing, for any relocating value n, since intuitively the shared areas are the same. The above version recomputes this information p times, where p is the number of distinct levels where the substituted variable occurs. This would not affect the quantity of sharing, it would only speed up its
computation, and since the code would be significantly more complicated we shall not do it here.

Although in some sense we share maximally a term with its substituted versions, we fail to propagate this sharing, since recursive exploration of a term where certain nodes are shared does not recognize this sharing, and will therefore undo this sharing by further substitutions. In order to preserve sharing, we ought to remember in a table pairs of addresses (original-term-node, substituted-term-node), in the spirit of traditional graph-copying algorithms. We shall ignore this optimization here.

Finally, a smarter use of indexes may be imagined, where lifting and substitution are delayed as much as possible, by keeping relocation indexes in the expressions themselves. However, this idea is not as easy as it sounds, since such relocation annotations do not commute easily with abstraction, and very quickly we run into the problem of manipulating complex annotations of the form “lift by $n_1$ all variables greater the $m_1$, and ...”. Clearly, we are not saying the last word on possible implementations of $\lambda$-calculus in the de Bruijn style.

2 Application to the Calculus of Constructions

2.1 Term and types

The Calculus of Constructions, originally described in Thierry Coquand’s thesis[12], refers to a family of formalisms which permit to describe both objects structured with types, and natural deduction proofs of higher-order logic. We thus have naturally two levels of descriptions:

```ocaml
#type level = Object | Proof;;
Type level defined
  Object : level
  | Proof : level
```

The two levels are intermixed in uniform term structures of a typed $\lambda$-calculus, where types are themselves terms of the same nature. At the level of proofs, we use the Curry-Howard isomorphism: propositions are seen as the types of their proofs.

We thus have two kinds of judgement:

- $\text{Judge}(M, T, \text{Object})$ means “Object $M$ has type $T$”.
- $\text{Judge}(M, P, \text{Proof})$ means “Proof $M$ proves proposition $P$”.

Such judgements refer implicitly to a global context of variable declarations and constant definitions. That is, we have possibly non-closed terms of a $\lambda$-calculus with constants. We shall come back later to the structure of the global environment. We may at this point define our types of terms and judgements:

```ocaml
#type constr =
#  # Rel of num (* bound variables *)
#  | Var of string * judgement (* free variables *)
#  | Const of string * judgement (* constants *)
#  | Prop (* type of propositions *)
```
# | Type of num (* universes *)
# | App of constr * constr (* application (M N) *)
# | Lambda of constr * constr (* abstraction [x:T]M *)
# | Prod of constr * constr (* product (x:T)M *)

#and judgement = Judge of constr * constr * level;;

Type constr defined
Rel : (num -> constr)
| Var : (string * judgement -> constr)
| Const : (string * judgement -> constr)
| Prop : constr
| Type : (num -> constr)
| App : (constr * constr -> constr)
| Lambda : (constr * constr -> constr)
| Prod : (constr * constr -> constr)

Type judgement defined
Judge : (constr * constr * level -> judgement)

The Rel variables are local variables implemented with de Bruijn indexers. The Var and Const refer to respectively variable declarations and constant definitions. Global identifiers are recognized by the parser as known in the environment as variable declarations or constant definitions, and the corresponding piece of the environment is pointed to by the corresponding term constructors Var and Const. This has the advantage of avoiding environment searches during type-checking. It has the drawback that our term structures are complicated dags sharing with the environment all the necessary information.

Both Prod and Lambda are operators which are binding in their second argument, the first one being the type of the bound variable. Lambda is λ-abstraction, whereas Prod is product formation for types, and universal quantification for propositions. Note our ambiguous use of the word “type”, since the type of a term is either a type, i.e. a term of type Type(i) for a certain i, or a proposition, i.e. a term of type Prop. In this last case, we use the analogy of propositions with types, identifying a proposition with the type of it proofs. We thus have a λ-calculus at two levels. At the level Object abstraction is used for expressing the functionality of the mathematical objects and proposition schemes, in the spirit of Church’s type theory. At the level Proof it corresponds to (intuitionistic) implication introduction in natural deduction.

The following function checks that its argument is a kind, i.e. of the form Prop or Type(_,), and returns the level of terms whose types are of that kind.

#let level_of_kind = function
# | Type(_,) -> Object
# | Prop     -> Proof
# | _        -> error "Not a proposition or a type";;
Value level_of_kind = <fun> : (constr -> level)

Note the similarity of our term structures with the linguistic structures of Automath. In the terminology of Automath, our structure extends Nederpelt’s Λ. However, we use it with a restricted notion of level, i.e. we have a regular language[19]. We distinguish between Prod and Lambda, in the spirit of AutPi. This was not done in the original calculus.
of Coquand[12]. We prefer to make the distinction now, because this entails unicity of types. We have also constants and δ-rules, in the spirit of ΛΔ[10]. More importantly, we have higher-order quantification, like in Girard’s system $F_\omega$, which makes the calculus significantly more powerful than both the Automath systems, and the Martin-Löf type theories. We may thus develop higher-order mathematics, as advocated by Scott[42]. In the jargon of proof theorists, the system is “non-predicative”.

2.2 Substitution

Substitution is a straightforward generalization of the ideas given in section 1.3 above. The descriptor lambda_descr is simply replaced by the descriptor

\begin{verbatim}
let constr_descr =
    ["App",[false;false]);
    ("Lambda",[false;true]);
    ("Prod",[false;true])];;
\end{verbatim}

which describes the binding effect of the term constructors. The functions lift and subst are appropriately adapted.

The main departure from pure $\lambda$-calculus is that we have a calculus with constants. We thus have several substitution functions for various uses:

\begin{verbatim}
subst1 : constr -> constr -> constr
(* (subst1 c1 c2) substitutes c1 for Rel(1) in c2 *)
subst2 : string -> constr -> constr
(* (subst2 str c) substitutes Rel(1) for Var(str,_) in c *)
subst_con : string -> constr -> constr -> constr
(* (subst_con str c1 c2) substitutes c1 for Const(str,_) in c2 *)
\end{verbatim}

Each of these functions is programmed with the help of the macro binding_morphism.

2.3 Equality

Equality of terms means inter-convertibility by $\beta$-conversion. Because the calculus is confluent and notherian, this could be decided by comparing the normal forms of the two terms. However this is not what we want in a calculus with constants. We want to verify equivalence of terms with as little constant expansion as possible, i.e. to try intensional equality before computing unfolding the constant definitions.

For instance, consider the step of proof which consists in applying a lemma L1 stating that every reflexive relation R is cyclic. We thus have, in the current context, a constant:

\begin{verbatim}
L1 : (T:Type)(R:T->T->Prop)(Reflexive R)->(Cyclic R)
\end{verbatim}

Assume that the current context contains declarations for a type T1, a relation R1 over T1, and a hypothesis H1 that R1 is reflexive. Now we want to be able to apply (L1 T1 R1 H1). The last application will involve verifying equality of two instances of the proposition (Reflexive R1). It would be absurd here to look up the definition of the concept Reflexive, and to expand to normal form the two propositions. We want to avoid going back to first principles, but to do as we usually do in first-order logic, when Reflexive
is a non-analysed binary predicate. Of course, in last resort, we must allow for possible constant expansion.

This motivates the introduction of a data type of *approximations*, which are used to compute head normal forms progressively.

```ocaml
#(* The two kinds of variables *)
#type reference =
#   Local of num
# | Global of string;;
Type reference defined
  Local : (num -> reference)
| Global : (string -> reference)

#type approximation =
#   Abstraction of constr * constr
# | Product of constr * constr
# | Variable of reference * constr list
# | Constant of (string * judgement) * constr list
# | Propconst
# | Typeconst of num;;
Type approximation defined
  Abstraction : (constr * constr -> approximation)
| Product : (constr * constr -> approximation)
| Variable : (reference * constr list -> approximation)
| Constant :
  ((string * judgement) * constr list -> approximation)
| Propconst : approximation
| Typeconst : (num -> approximation)

#(* One step of approximation *)
#let rec approx stack = hnf
#where rec hnf = function
#   Rel(n) -> Variable(Local(n),stack)
# | Var(name,_) -> Variable(Global(name),stack)
# | Const(n_j) -> Constant(n_j,stack) (* No expansion! *)
# | Prop -> if stack=[] then Propconst
# | Type(n) -> if stack=[] then Typeconst(n)
# | else anomaly "Type cannot be applied"
# | App(c1,c2) -> approx (c2::stack) c1
# | Lambda(c,c') -> (match stack with
#       [] -> Abstraction(c,c')
#       | arg1::rest -> approx rest (subst1 arg1 c'))
# | Prod(c,c') -> if stack=[] then Product(c,c')
# | else anomaly "Product cannot be applied";;
Value approx = <fun> :
  (constr list -> constr -> approximation)
```
#let approxim c = approx [] c;;
Value approxim = <fun> : (constr -> approximation)

We are now ready to describe type equality, which proceeds by \(\lambda\)-conversion and constant expansion. This last operation is delayed as much as possible.

#(* Constant expansion *)
#let expand = function
# Constant((_,Judge(c,_)),stack) -> approx stack c
#| _ -> anomaly "Trying to expand a non-constant";;
Value expand = <fun> : (approximation -> approximation)

#(* equality of terms modulo conversion *)
#let rec conv term1 term2 = eqappr (approxim term1,approxim term2)
# where rec eqappr = function
#   (Abstraction(c1,c2),Abstraction(c'1,c'2)) -> conv c1 c'1
#     & conv c2 c'2
#| (Product(c1,c2),Product(c'1,c'2)) -> conv c1 c'1 & conv c2 c'2
#| (Variable(n1,l1),Variable(n2,l2)) -> (n1=n2) &
#   (length l1 = length l2) & for_all2 conv l1 l2
#| (Propconst,Propconst) -> true
#| ((Typeconst(u1),Typeconst(u2)) -> u1=u2
#| ((Constant(s1,l1) as appr1),(Constant(s2,l2) as appr2)) ->
#   (* try first intensional equality *)
#   (eq(s1,s2) & (length(l1) = length(l2)) & (for_all2 conv l1 l2))
#   (* else expand the second occurrence (arbitrary heuristic) *)
#   or eqappr(appr1,expand appr2)
#| ((Constant(_, as appr1),appr2) -> eqappr(expand appr1,appr2)
#| (appr1,(Constant(_, as appr2)) -> eqappr(appr1,expand appr2)
#| _ -> false;;
Value conv = <fun> : (constr -> constr -> bool)

The next function effects one step of head normal form leading to Prop, Type, or Prod. It is used for making explicit the type of a construction.

#let hnftype = apprec []
#where rec apprec stack = app_stack
#where rec app_stack = function
#   Rel(_) -> error "Typing error 1"
#| Var(_) -> error "Typing error 2"
#| Const(_,Judge(c,_)) -> app_stack(c)
#| App(c1,c2) -> apprec (c2::stack) c1
#| Lambda(_,c) -> (match stack with
#   [] -> error "Typing error 3"
#     | c':rest -> apprec rest (subst1 c' c))
# | (* Prod/Prop/Type *)
2.4 Structure of the environment

The environment contains variable declarations, constant definitions, values waiting to be applied, and types waiting to be used as coercions. We shall explain the last two kinds of items in the next section.

```
#type declaration =
#  | Vardecl of string * judgement
#  | Constdecl of string * judgement
#  | Value of judgement
#  | Cast of judgement
#and context == declaration list;;
```

Type declaration defined

```
  Vardecl : (string * judgement -> declaration)
  | Constdecl : (string * judgement -> declaration)
  | Value : (judgement -> declaration)
  | Cast : (judgement -> declaration)
```

Type context abbreviates declaration list

We now declare the he initial state, consisting of the empty initial context, and the initial judgement, stating that Prop is an Object of type Type(0).

```
#let ENV = ref ([:].context)    (* The current construction *)
#and VAL = ref (Prop)          (* Its type *)
#and TYP = ref (Type(0))       (* Its level *);;
Value ENV = (ref []) : context ref
Value VAL = (ref Prop) : constr ref
Value TYP = (ref (Type 0)) : constr ref
Value LEV = (ref Object) : level ref
```

2.5 A digression on the meaning of inference rules

The constructive engine may be thought of as some kind of loom, where we weave back and forth between the environment and the current value. The fabric is produced whenever we build a new component of the environment, by taking the current judgement to build a new variable declaration or a new constant definition. The fabric may be taken back by discharging variables as abstractions or products, forming arbitrary new patterns.

This “loom” implementation is in some way the spirit of natural deduction, as opposed to sequent calculus, in which proofs may be seen as produced by cooperating machines working in parallel. In some sense this is a deep distinction between natural deduction logical frameworks, and sequent calculus logical frameworks. For instance, compare and_intro:

\[
\frac{\Gamma \vdash A \quad \Gamma \vdash B}{\Gamma \vdash A \land B} \quad \text{natural}
\]
\[
\frac{\Gamma \vdash A \quad \Delta \vdash B}{\Gamma \cup \Delta \vdash A \land B}
\]

In the sequent formulation, \( \Gamma \) and \( \Delta \) may be thought of as sets of propositions. In the natural formulation, \( \Gamma \) may be thought of as a list constructed progressively. However, the important distinction is not so much on the structural rules. It is that the two occurrences of \( \Gamma \) on the numerator of the natural rule do not denote two lists that somehow happen to be equal structurally: they denote the same shared object. Actually, the left top occurrence may be considered the binding occurrence of \( \Gamma \), whereas the right top one, as well as the one in the denominator, may be considered residuals, or pointers to the data structure which was the state of the environment when applying the rule. Similarly, the occurrences of \( A \) and \( B \) in the denominator denote pointers to the propositions that have been bound to their respective binding occurrence on the numerator.

Thus we may regard inference rules of natural deduction formalisms as direct specifications of elementary machine operations, with registers for the environment, the current proof, and the currently proved proposition. This is the point of view we take for our implementation of the Calculus of Constructions.

It should be noticed that this point of view may not be adequate for theorem proving, as opposed to theorem checking. For synthesizing proofs, the sequent formulations may actually be preferable. The point we want to emphasize (and we believe has not been strongly stressed before) is first that natural versus sequent formulations of logic is not a choice based on aesthetic choice, but is important for its pragmatic use, and second that it suggests implementation techniques, since the meaning of meta-variables in the rules is quite different.

Once we notice that meta-variables in inference rules denote shared objects, it is natural to distinguish, in the various occurrences of such schematic variables, one binding occurrence, instantiated by pattern-matching, the others denoting residuals in the sense of \( \lambda \)-calculus, i.e. pointers to the corresponding substructure. For instance, consider the usual natural-deduction formulation of arrow-elim, i.e. application or modus ponens:

\[
\frac{\Gamma \vdash M : A \rightarrow B \quad \Gamma \vdash N : A}{\Gamma \vdash (M \, N) : B}
\]

In order to make explicit the flow of information, when using this rule for proof-checking, it is obvious that the binding occurrences of \( \Gamma \), \( M \) and \( N \) are in the denominator of the rule, whereas the binding occurrence of \( B \) is in the numerator. Concerning \( A \), we have a problem. The one in the right argument of the rule may be considered binding: “Let \( A \) be the type of term \( N \) in environment \( \Gamma \).” The one in the left argument, also, could be considered binding in a system where unicity of types hold. Here, where types are only unique up to \( \beta \)-conversion, it could mean: “Convert the type of term \( M \) in environment \( \Gamma \) to its head normal form, check that it has the shape \( A \rightarrow B \).” But, in either case, we do not mean that the types of \( M \) and \( N \) should share a common substructure, but merely that the corresponding substructures ought to be equal (and here, actually, a recursive exploration to check this fact is meant). Thus, what we mean to specify is a rule that says: “Let \( C \) be the type of term \( M \) in environment \( \Gamma \). Convert \( C \) to its head normal form. Check that it has the shape \( A' \rightarrow B \). Check that \( A \) and \( A' \) are convertible.”

We are now close to a complete specification of the proof checker. Two details remain.

The first detail concerns the order in which \( M \) and \( N \) are actually typechecked in a sequential machine. There are two possible interpretations of application as a term con-
structor: the left-sequential one (first \(M\) and then \(N\)), and the right-sequential one (the opposite order). In either case, some explicit memorisation of the intermediate type shall be needed. We remark that this memorisation cannot be done simply in an auxiliary stack, since the proper scoping must be enforced. We are lead to stack the corresponding judgement as an item in the environment. In our implementation, we choose the right-sequential interpretation, and we are thus lead to an inference rule (where binding occurrences are underlined):

\[
\frac{\Gamma \vdash N : A \quad \Gamma \vdash M : C \quad C \triangleright A' \rightarrow B \quad A \equiv A'}{\Gamma \vdash (M \ N) : B}
\]

which is in turn implemented as the composition of two unary transition rules, with explicit stacking in the environment:

\[
\begin{align*}
\Gamma \vdash N : B & \quad \implies \quad \Gamma ; N : B \vdash \text{stack} \\
\Gamma ; N : B \vdash M : C & \quad \implies \quad (C \triangleright A' \rightarrow B, A \equiv A') \quad \Gamma \vdash (M \ N) : B \quad \text{pop \ apply}
\end{align*}
\]

In stack_value, the notation \(\Gamma ; N : B \vdash\) stands for stacking the current judgement in the environment without changing it. We are thus lead to the view of elementary machine operations (the conditional transition rules) corresponding to an explicit sequentialisation of inference rules. The memorisation insures that these elementary commands may be used independently of each other.

The second detail concerns conversion in the presence of the constant definitions, which are definitional equalities; in such systems the conversion depends on these equalities, and thus of the environment, in which they are declared. That is, in order to be completely rigorous we ought to write \(\Gamma \vdash A \equiv A'\) above.

To a certain extent the situation may be compared to PROLOG. The inference rules, with suitable detail, correspond rather directly to PROLOG clauses. The relations \(\triangleright\) and \(\equiv\) are executable predicates, and the underlining of binding occurrences correspond to input specifications à la Concurrent Prolog. This point of view is close to the one of the logical framework Typol[30]. The transition rules correspond to the basic instructions of a sequential PROLOG machine. One may argue that this low-level description is not really needed for the user of the logical environment. However, this amount of detail may be needed to derive useful meta-mathematical properties.

In the following, we shall describe our engine in terms of the CAML functions implementing its basic transition rules. The higher-level inference rules are given as comments.

2.6 Initialization

2.6.1 Resetting the current judgement

```caml
#let reset_current () =
# VAL := Prop;
# TYP := Type(0);
# LEV := Object;;
Value reset_current = <fun> : (unit -> level)
```
2.6.2 Resetting, pushing and popping the environment

```ocaml
#let reset_env () =
# ENV := []
#and push_env declaration =
# ENV := declaration::!ENV
#and pop_env () = match !ENV with
# \[\] -> error "Empty environment"
# | decl::env -> ENV := env; decl;;
Value reset_env = <fun> : (unit -> context)
Value push_env = <fun> : (declaration -> context)
Value pop_env = <fun> : (unit -> declaration)
```

2.6.3 Searching the environment

Note that we do not need to relocate the judgements stacked in the environment, since we do not use indexes, but identifiers for the globals.

```ocaml
#let search name = search_rec !ENV
# where rec search_rec = function
# \[\] -> error(name ^ " not declared")
# | decl::rest -> match decl with
# # Vardecl(s,_) -> if s=name then decl else search_rec rest
# # | Constdecl(s,_) -> if s=name then decl else search_rec rest
# # | _ -> search_rec rest;;
Value search = <fun> : (string -> declaration)
```

2.7 The basic machine operations

There are few basic machine operations, partitioned into two kinds: the ones that build up the environment, and the ones that build up the current construction. For each such command, we give first the inference rule, then the CAML function which performs the corresponding machine instruction.

2.7.1 Introducing a new hypothesis

\[
\frac{\Gamma \vdash M : Prop}{\Gamma; x : M \vdash}
\]

\[
\frac{\Gamma \vdash M : Type(i)}{\Gamma; x : M \vdash}
\]

```ocaml
#let assume name =
# let declaration =
# let typ = hnftype !TYP
# in let lev = level_of_kind typ
# in Vardecl(name, Judge(!VAL,typ,lev))
# in push_env declaration;;
Value assume = <fun> : (string -> context)
```
2.7.2 Introducing a new definition
\[
\Gamma \vdash M : T \\
\Gamma ; x = M : T \vdash
\]

```ml
#let declare name =
#  let declaration = Constdecl(name, Judge(!VAL, !TYP, !LEV))
#  in push_env declaration;;
Value declare = <fun> : (string -> context)
```

2.7.3 Global Introduction
\[
\begin{align*}
\Gamma = \Gamma_1; x : \Gamma_2; \Gamma_2 & \quad \Gamma = \Gamma_1; x = V : \Gamma_2; \Gamma_2 \\
\Gamma \vdash x : \Gamma_2 & \quad \Gamma \vdash x : \Gamma_2
\end{align*}
\]

```ml
#let consider name =
#  match (search name) with
#    Constdecl((_, Judge(_, typ, lev)) as constant) ->
#      (TYP:=typ;
#       LEV:=lev;
#       VAL:=Const(constant))
#    | Vardecl((_, Judge(typ, _, lev)) as variable) ->
#      (TYP:=typ;
#       LEV:=lev;
#       VAL:=Var(variable));;
Warning: 1 partial match in this phrase
Value consider = <fun> : (string -> constr)
```

2.7.4 Prop intro
\[
\Gamma \vdash Prop : Type(1)
\]

```ml
#let proposition () = VAL:=Prop; TYP:=Type(1); LEV:=Object;;
Value proposition = <fun> : (unit -> level)
```

2.7.5 Type intro
\[
\Gamma \vdash Type(i) : Type(i + 1)
\]

```ml
#let universe num =
#  if num<1 then error "Illegal universe level"
#  else VAL:=Type(num); TYP:=Type(num+1); LEV:=Object;;
Value universe = <fun> : (num -> level)
```
2.7.6 App intro

\[
\Gamma \vdash M : (x : B) C \
\Gamma \vdash N : A \
\Gamma \vdash A \equiv B \\
\Gamma \vdash (M \; N) : [N/x] C
\]

As explained above, this rule splits into two transitions rules:

#(* Stacks a value for future application *)
#let stack_value () =
# let declaration = Value(Judge(!VAL,!TYP,!LEV))
# in push_env declaration;;
Value stack_value = <fun> : (unit -> context)

#(* Extracts the last pushed value in environment *)
#let unstack_value () =
# let match !ENV with
#    Value(j)::rest -> ENV:=rest; j
#    | _ -> error "Last item not a value";;
Value unstack_value = <fun> : (unit -> judgement)

#let pop_apply () =
# let match hnftype !TYP with
#    Prod(typarg,typres) ->
#    let (Judge(val,typ,lev)) = unstack_value()
#    in if conv typ typarg then (VAL:=App(!VAL,val);
#      TYP:=subst1 val typres)
#      else error "Application would violate typings"
#    | _ -> error "Non-functional construction";;
Value pop_apply = <fun> : (unit -> constr)

2.7.7 Discharging definitions

We allow forgetting a constant by replacing its value in the current judgement.

\[
\Gamma;x = M : T \vdash N : A \\
\Gamma \vdash [x/M] N : [x/M] A
\]

#let pop_const () =
# let match !ENV with
#    [] -> error "No constant in environment"
#    | Constdecl(name,Judge(val,_))::rest ->
#      VAL:=subst_con name val !VAL;
#      TYP:=subst_con name val !TYP;
#      ENV:=rest
#      | _ -> error "Last item not a constant";;
Value pop_const = <fun> : (unit -> context)

Variables may be discharged in two ways: for forming abstractions and for forming products. Both rules use as an auxiliary:
#let unstack_var () =
#  match !ENV with
#    []     -> error "No hypothesis in current context"
#    | Vardecl(var)::rest  -> ENV:=rest; var
#    | _     -> error "Last item not a variable";;
Value unstack_var = <fun> : (unit -> string * judgement)

2.7.8 Lambda Introduction

\[ \Gamma; x : M \vdash N : P \quad \Gamma \vdash [x : M]N : (x : M)P \]

#let abs_var () =
#  let (name,Judge(typ,_,_)) = unstack_var()
#  in VAL:=Lambda(typ,subst2 name !VAL);
#  TYP:=Prod(typ,subst2 name !TYP);;
Value abs_var = <fun> : (unit -> constr)

2.7.9 Product Introduction

Here we have the union of 3 inference rules:

\[ \Gamma; x : M \vdash N : Prop \quad \Gamma \vdash (x : M)N : Prop \]

\[ \Gamma \vdash M : Type(j) \quad \Gamma; x : M \vdash N : Type(i) \quad \Gamma \vdash (x : M)N : Type(max(i,j)) \]

\[ \Gamma \vdash M : Prop \quad \Gamma; x : M \vdash N : Type(i) \quad \Gamma \vdash (x : M)N : Type(i) \]

The last two rules appear to be binary. However, they correspond to a unary transition, since the type of \( M \) is explicit in the judgement stored in the variable declaration. Here is an example where the rules of inference do not carry enough information: we do not need to use a meta theorem saying that if \( \Gamma; x : M \) is a well-formed environment, then either \( \Gamma \vdash M : Type(j) \) or \( \Gamma \vdash M : Prop \). This fact is actually explicit from the way the variable declarations are structured in the machine.

#let gen_var () =
#  if !LEV = Proof then error "Proof objects can only be abstracted";
#  let (name,Judge(typ,kind,_,_)) = unstack_var()
#  in (TYP:=(match hnftype !TYP with
#    Prop -> Prop (* quantification : TYP stays Prop *)
#    | Type(n) -> (* product *)
#    Type(match kind with Prop -> n | Type(m) -> max m n)
#    | _     -> error "Product allowed only on types"));
#  VAL:=Prod(typ,subst2 name !VAL));;
Warning: 1 partial match in this phrase
Value gen_var = <fun> : (unit -> constr)
2.10 Type conversion

\[
\begin{align*}
\Gamma &\vdash M : A & \Gamma &\vdash B : Prop & \Gamma &\vdash A \equiv B \\
\Gamma &\vdash M : B \\
\Gamma &\vdash M : A & \Gamma &\vdash B : Type(i) & \Gamma &\vdash A \equiv B \\
\Gamma &\vdash M : B
\end{align*}
\]

As for application, this pair of rules splits into two transition rules:

```plaintext
(* Stacking a type for future coercion *)
#let stack_cast () =
#  let typ = hnftype(!TYP)
#  in let lev = level_of_kind typ
#  in let declaration = Cast(Judge(!VAL,typ,lev))
#  in push_env declaration;;
Value stack_cast = <fun> : (unit -> context)

#let unstack_cast () =
#  match !ENV with
#    | [] -> error "No cast in current context"
#    | Cast(j)::rest -> ENV:=rest;j
#    | _  -> error "Last item not a cast";;
Value unstack_cast = <fun> : (unit -> judgement)

#let cast () =
#  let (Judge(typ,_,lev)) = unstack_cast()
#  in if lev<>!LEV then error "Wrong level for coercion"
#  if conv !TYP typ then TYP:=typ
#  else error "Cannot coerce to intended type";;
Value cast = <fun> : (unit -> constr)

2.8 Higher-level commands

2.8.1 Sections

The machine is equipped of a hierarchical description mechanism which permits to declare variables and define constants within a local scope. This mechanism is operated through the opening and closing of named sections. Variables and constants are declared with a certain strength controlling their lifetime as follows. When \( n \) sections are opened, the possible strengths of notions are integers between 0 and \( n \). A notion of strength 0 is local to the current section, a notion of greater strength will survive the closing of the current section. When a section is closed, the corresponding segment of the environment is popped and processed as follows. Stacked casts and values are forgotten, with a warning. Local constants disappear by substitution. Local variables are discharged, by abstraction in values, and by product/quantification in types. Thus the variables and constants declared with a positive strength will be kept, under the same name, but with added functionality.

We shall not discuss further this sections mechanism, which would require a more precise explanation, and whose design is not considered definitive yet. For the present paper, let us just consider this structuring mechanism as high-level commands, which
could be implemented by macro-generation of the elementary operations of the engine, by keeping separately the strength information. In the current implementation, however, section headers are items in the environment.

2.8.2 Inductive definitions

It is possible to describe complex inductive definitions of types, constructors of those types, and induction/recursion principles on those types. We shall not describe further this facility, which is described in [39], and which ought to be superseded in next versions of the calculus by the addition, at the terms level, of (strongly positive) recursive type definitions.

3 The mathematical vernacular

The constructive engine is generally not operated directly. Its commands are usually compiled from a higher level notation for mathematics, called the Mathematical Vernacular. The idea of describing mathematical arguments in a mathematical vernacular language is due to de Bruijn[8].

3.1 A small vernacular syllabus

Our mathematical vernacular is very rudimentary at present. Here is a succinct description of its main constructs.

There are two sub-languages:

- a language of expressions, used to denote terms, propositions, types, proofs, etc...
- a language of commands, used to write mathematical definitions, postulate axioms and hypotheses, state and proof lemmas and theorems.

3.1.1 Expressions

Names are identifiers in the sense of CAML. Two special identifiers “Prop” and “Type” are reserved.

Expressions are defined recursively as follows:

- names are expressions.
- Prop is an expression.
- Type(n) is an expression, for n > 0. Type is an abbreviation for Type(1).
- (M N) is an expression when M and N are expressions. It stands for “apply function M to its argument N”. This notation is generalized to (M N1 N2 ... Np).
- (x : M)Nx is an expression if x is a name, and M and Nx are expressions. It stands for the logical proposition “for every x of type M we have Nx” when Nx stands for a proposition, and for the type “product of Nx indexed by M” when Nx stands for a type. This notation is extended to accomodate (x1, x2, ..., xn : M)N as an
abbreviation for \((x_1 : M)(x_2 : M)...(x_n : M)N\). When \(x\) does not occur in \(N\), the expression \((x : M)N\) may also be written as \(M \to N\).

- \([x : M]N_x\) is an expression if \(x\) is a name, and \(M\) and \(N_x\) are expressions. It stands for the function which associates to its argument \(x\) of type \(M\) the value \(N_x\). This notation is extended to accommodate \([x_1, x_2, ..., x_n : M]N\) as an abbreviation for \([x_1 : M][x_2 : M]...[x_n : M]N\).

- \(let x = M in N_x\) is an expression if \(x\) is a name, \(M\) and \(N_x\) are expressions. It stands for the expression \(N_x\), in which every occurrence of the name \(x\) is replaced by the expression \(M\).

### 3.1.2 Commands

A mathematical text is seen as a list of commands to be executed. The type-checking of expressions that are arguments to commands ensures that the definitions make sense, and that the proofs prove the statements of theorems.

- **Hypothesis** \(x : T\)
  - defines a new hypothesis \(x\) of type the expression \(T\)

- **Variable** \(x : T\)
  - variant of the previous command

- **Hypotheses** \(x,y,z : T\)
  - for multiple declarations sharing the type \(T\)

- **Variables** \(x,y,z : T\)
  - idem

- **Axiom** \(x : A\)
  - the proposition \(A\) is assumed as an axiom named \(x\)

- **Type** \(x\)
  - Abbreviates Variable \(x : Type\)

- **Proposition** \(x\)
  - Abbreviates Variable \(x : Proposition\)

- **Definition** \(x\ M\)
  - Checks that \(M\) is well-typed, and defines it under name \(x\)

- **Name** \(x\ M\)
  - Local version of Definition

- **Global** \(x : T = M\)
  - Checks that \(M\) is well-typed consistently with type \(T\), and defines it under name \(x\)

- **Let** \(x : T = M\)
  - Local version of Global
3.2 A full exemple: Newman’s lemma

We give here the listing of a full exemple as written in the current system. Newman’s lemma states that every noetherian relation is confluent if it is locally confluent. The proof is the same as the one explained in [25], and given in an older version of the calculus in [15]. A discussion of the definition of induction principles in the Calculus of Constructions may be found in [27].

This section of vernacular assumes prior loading of a standard prelude, defining logical primitives.

We start with an auxiliary module of definitions concerning binary relations, where notions such as transitive-reflexive closure \( \text{Rstar} \) of relation \( R \) are defined.

\[
\text{Variable} \ A : \text{Type.} \\
\text{Variable} \ R : A \to A \to \text{Prop.}
\]

\[
(* \text{Definition of the reflexive-transitive closure} \text{R* of R} *) \\
(* \text{Smallest reflexive P containing R o P} *)
\]

\[
\text{Definition} \ \text{Rstar} [x,y:A](P:A\to A\to \text{Prop}) \\
\quad ((u:A)(P u u)) \to ((u:A)(v:A)(w:A)(R u v) \to (P v w) \to (P u w)) \to (P x y).
\]

\[
\text{Theorem} \ \text{Rstar_reflexive} \ (x:A)(\text{Rstar} x x) \\
\text{Proof} \ [x:A][P:A\to A\to \text{Prop}] \\
\quad [h1:(u:A)(P u u)][h2:(u:A)(v:A)(w:A)(R u v) \to (P v w) \to (P u w)] \\
\quad (h1 x).
\]

\[
\text{Theorem} \ \text{Rstar_R} \ (x:A)(y:A)(z:A)(R x y) \to (\text{Rstar} y z) \to (\text{Rstar} x z)
\]

End Ind.

Theorem Newman (x:A)(confluence x)
Proof [x:A](Hyp1 x confluence Ind_proof).
End Newman.

The complete proof-checking of this example takes 4 seconds on a SUN 3-60 in the current version 4.9 of our implementation of the calculus, using CAML version 2.6.

We would like to stress the fact that this seemingly purely declarative piece of math-
ematics is actually compiled and run on the constructive engine. This is an extremely concrete illustration that “the mathematician builds the universe he lives in.”

**Conclusion**

We have presented here only a facet of our implementation of the calculus. Other uses of the system are possible. For instance, an extractor computes the information contents of proofs with special annotations. A theorem-prover, based on the proper adaptation of LCF tactics, searches for proofs under the user’s guidance. The incorporation of the tactics language in the vernacular would be a first step towards a completely formal description of mathematical theories in a language close to the usual mathematics practice. Extensions of the calculus are considered, principally recursive types.

We have given in this note a rather complete description of the basic bloc, the Constructive Engine. The algorithms presented are directly executable CAML programs, taken from the actual implementation. This is a first attempt at using CAML as a publication language.
