### The formal verification of compilers

Xavier Leroy

Inria Paris

DeepSpec Summer School 2017

### Prologue

Mechanized semantics and its applications

### Formal semantics of programming languages

Provide a mathematically-precise answer to the question

What does this program do, exactly?

### What does this program do, exactly?

```
#include <stdio.h>
int 1; int main(int o, char **0,
int I)\{char c.*D=0[1]:if(o>0)\}
for(1=0:D[1
                         ]:D[1
++]-=10){D [1++]-=120:D[1]-=
110; while (!main(0,0,1))D[1]
    20: putchar((D[1]+1032)
+=
/20 ) ;}putchar(10);}else{
         (D[I]+82)%10-(I>1/2)*
c=o+
(D[I-1+I]+72)/10-9;D[I]+=I<0?0
:!(o=main(c/10,0,I-1))*((c+999)
)%10-(D[I]+92)%10);}return o;}
```

(Raymond Cheong, 2001)

X. Leroy (Inria) Compiler verification DSSS 2017 4/226

### What does this program do, exactly?

```
#include <stdio.h>
int 1; int main(int o, char **0,
int I)\{char c.*D=0[1]:if(o>0)\}
for(1=0:D[1
                         1:D[1
++]-=10){D [1++]-=120:D[1]-=
110; while (!main(0,0,1))D[1]
    20: putchar((D[1]+1032)
+=
/20 ) ;}putchar(10);}else{
         (D[I]+82)\%10-(I>1/2)*
c=o+
(D[I-1+I]+72)/10-9;D[I]+=I<0?0
:!(o=main(c/10,0,I-1))*((c+999)
)%10-(D[I]+92)%10);}return o;}
```

(Raymond Cheong, 2001)

(It computes arbitrary-precision square roots.)

X. Leroy (Inria) Compiler verification DSSS 2017 4 / 226

#### What about this one?

```
#define crBegin static int state=0; switch(state) { case 0:
#define crReturn(x) do { state=_LINE__; return x; \
                          case __LINE__:; } while (0)
#define crFinish }
int decompressor(void) {
    static int c, len;
                                             (Simon Tatham,
    crBegin;
                                             author of PuTTY)
   while (1) {
        c = getchar();
        if (c == EOF) break;
        if (c == 0xFF) {
            len = getchar();
            c = getchar();
            while (len--) crReturn(c);
        } else crReturn(c);
    crReturn(EOF);
    crFinish;
```

#### What about this one?

```
#define crBegin static int state=0; switch(state) { case 0:
#define crReturn(x) do { state=_LINE__; return x; \
                          case __LINE__:; } while (0)
#define crFinish }
int decompressor(void) {
    static int c, len;
                                             (Simon Tatham,
    crBegin;
                                             author of PuTTY)
   while (1) {
        c = getchar();
        if (c == EOF) break;
        if (c == 0xFF) {
            len = getchar();
            c = getchar();
                                             (It's a co-routined version of a
            while (len--) crReturn(c);
        } else crReturn(c);
                                             decompressor for run-length
                                             encoding.)
    crReturn(EOF);
    crFinish;
```

### When is formal semantics necessary?

- When English prose is not enough.
   (e.g. language standardization documents.)
- A prerequisite to formal program verification.
   (Program proof, model checking, static analysis, etc.)
- A prerequisite to building reliable programming tools.
   (Programs that operate over programs: compilers, code generators, program verifiers, type-checkers, . . . )

#### Is this program transformation correct?

#### Is this program transformation correct?

```
struct list { int head; struct list * tail; };
struct list * foo(struct list ** p)
 return ((*p)->tail = NULL);
                                           (*p)->tail = NULL;
                                           return (*p)->tail;
No, not if p == &(1.tail) and 1.tail == &1 (circular list).
```

#### What about this one?

```
double dotproduct(int n, double * a, double * b)
{
    double dp = 0.0;
    int i;
    for (i = 0; i < n; i++) dp += a[i] * b[i];
    return dp;
}</pre>
```

Compiled for the Alpha processor with all optimizations and manually decompiled back to  $\mathsf{C}\dots$ 

```
double dotproduct(int n, double * a, double * b)
ł
     double dp. a0, a1, a2, a3, b0, b1, b2, b3;
     double s0, s1, s2, s3, t0, t1, t2, t3;
    int i, k;
     dp = 0.0:

#### This lecture

Using the Coq proof assistant, formalize some representative program transformations and static analyses, and prove their correctness.

In passing, introduce the semantic tools needed for this effort.

#### Lecture material

http://gallium.inria.fr/~xleroy/courses/DSSS-2017/

- The Coq development (source archive + HTML view).
- These slides.
- Further reading.

#### Course outline

- Compiling IMP to a simple virtual machine; first compiler proofs; notions of semantic preservation.
- ② More on semantics: big-step, small-step, small-step with continuations. Finishing the proof of the IMP  $\rightarrow$  VM compiler.
- Verification of optimizing program transformations (dead code elimination, register allocation) based on a static analysis (liveness analysis).
- Compiler verification "in the large": a tour of CompCert.

Home work: the recommended exercises, plus optional exercises, or a mini-project (with much guidance), or a full project (with little guidance).

#### Part I

# Compiling IMP to virtual machine code

## Compiling IMP to virtual machine code

- Reminder: the IMP language
- The IMP virtual machine
- The compiler
- 4 Verifying the compiler: first results

### Reminder: the IMP language

(From Benjamin Pierce's "Logical Foundations" course.)

A prototypical imperative language with structured control flow.

Arithmetic expressions:

$$a ::= n \mid x \mid a_1 + a_2 \mid a_1 - a_2 \mid a_1 \times a_2$$

Boolean expressions:

$$b := true \mid false \mid a_1 = a_2 \mid a_1 \le a_2 \mid not \ b \mid b_1 \ and \ b_2$$

Commands (statements):

```
c ::= SKIP (do nothing)

|x ::= a (assignment)

|c_1;; c_2 (sequence)

|IFB \ b \ THEN \ c_1 \ ELSE \ c_2 \ FI (conditional)

|WHILE \ b \ DO \ c \ END (loop)
```

#### Reminder: IMP's semantics

As defined in file Imp.v of "Logical Foundations":

• Evaluation function for arithmetic expressions

Evaluation function for boolean expressions

• Evaluation predicate for commands (in big-step operational style)

$$c/st \Rightarrow st'$$

(st ranges over variable states:  $id \rightarrow nat$ .)

### Execution models for a programming language

Interpretation:

the program is represented by its abstract syntax tree. The interpreter traverses this tree during execution.

### Execution models for a programming language

Interpretation:

the program is represented by its abstract syntax tree. The interpreter traverses this tree during execution.

Compilation to native code: before execution, the program is translated to a sequence of machine instructions, These instructions are those of a real microprocessor and are executed in hardware.

### Execution models for a programming language

- Interpretation:
  - the program is represented by its abstract syntax tree. The interpreter traverses this tree during execution.
- Compilation to native code: before execution, the program is translated to a sequence of machine instructions, These instructions are those of a real microprocessor and are executed in hardware.
- Ompilation to virtual machine code: before execution, the program is translated to a sequence of instructions, These instructions are those of a virtual machine. They do not correspond to that of an existing hardware processor, but are chosen close to the basic operations of the source language. Then,
  - either the virtual machine instructions are interpreted (efficiently)
  - or they are further translated to machine code (JIT).

# Compiling IMP to virtual machine code

- Reminder: the IMP language
- 2 The IMP virtual machine
- 3 The compiler
- Werifying the compiler: first results

#### The IMP virtual machine

#### Components of the machine:

- The code *C*: a list of instructions.
- The program counter *pc*: an integer, giving the position of the currently-executing instruction in *C*.
- The store st: a mapping from variable names to integer values.
- The stack  $\sigma$ : a list of integer values (used to store intermediate results temporarily).

#### The instruction set

```
i := Iconst(n)
                                push n on stack
                                push value of x
     Ivar(x)
     Isetvar(x)
                                pop value and assign it to x
     Tadd
                                pop two values, push their sum
     Tsub
                                pop two values, push their difference
     Tm117
                                pop two values, push their product
                                unconditional jump forward
     Ibranch_forward(\delta)
     Ibranch_backward(\delta)
                                unconditional jump backward
                                pop two values, jump if =
     Ibeq(\delta)
     Ibne(\delta)
                                pop two values, jump if \neq
     \mathsf{Ible}(\delta)
                                pop two values, jump if \leq
     Ibgt(\delta)
                                pop two values, jump if >
                                end of program
     Ihalt
```

By default, each instruction increments pc by 1. Exception: branch instructions increment it by  $1+\delta$  (forward) or  $1-\delta$  (backward).

( $\delta$  is a branch offset relative to the next instruction.)

# Example

stack	$\epsilon$	12	1 12	13	$\epsilon$
store	$x \mapsto 12$	$x \mapsto 12$	$x \mapsto 12$	$x \mapsto 12$	$x \mapsto 13$
p.c.	0	1	2	3	4
code	Ivar(x);	Iconst(1);	   Iadd;	Isetvar(x);	Ibranch_ backward(5)

X. Leroy (Inria)

#### Semantics of the machine

Given by a transition relation (small-step), representing the execution of one instruction.

DSSS 2017

#### Executing machine programs

#### By iterating the transition relation:

- Initial states: pc = 0, initial store, empty stack.
- Final states: pc points to a halt instruction, empty stack.

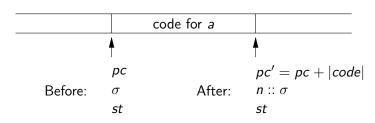

```
Definition mach terminates (C: code) (s init s fin: state) :=
  exists pc,
  code at C pc = Some Ihalt /\
  star (transition C) (0, nil, s_init) (pc, nil, s_fin).
Definition mach_diverges (C: code) (s_init: state) :=
  infseq (transition C) (0, nil, s_init).
Definition mach_goes_wrong (C: code) (s_init: state) :=
  (* otherwise *)
(star is reflexive transitive closure. See file Sequences.v.)
```

# Compiling IMP to virtual machine code

- Reminder: the IMP language
- 2 The IMP virtual machine
- The compiler
- 4 Verifying the compiler: first results

#### Compilation of arithmetic expressions

General contract: if a evaluates to n in store st,

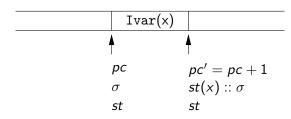

Compilation is just translation to "reverse Polish notation".

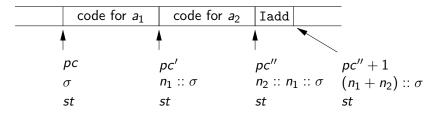

(See function compile\_aexpr in Compil.v)

#### Compilation of arithmetic expressions

Base case: if a = x,

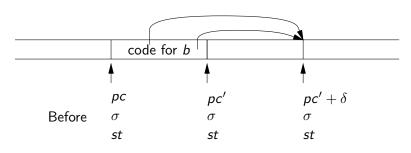

Recursive decomposition: if  $a = a_1 + a_2$ ,

#### Compilation of boolean expressions

#### compile\_bexp b cond $\delta$ :

skip  $\delta$  instructions forward if b evaluates to boolean cond continue in sequence if b evaluates to boolean  $\neg cond$ 

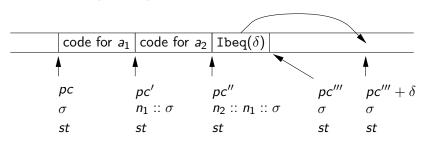

After (if result 
$$\neq cond$$
)

After (if result  $= cond$ )

### Compilation of boolean expressions

A base case:  $b = (a_1 = a_2)$  and cond = true:

X. Leroy (Inria) Compiler verification DSSS 2017

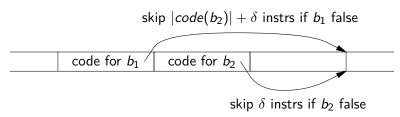

### Short-circuiting "and" expressions

If  $b_1$  evaluates to false, so does  $b_1$  and  $b_2$ : no need to evaluate  $b_2$ !

 $\rightarrow$  In this case, the code generated for  $b_1$  and  $b_2$  should skip over the code for  $b_2$  and branch directly to the correct destination.

### Short-circuiting "and" expressions

If cond = false (branch if  $b_1$  and  $b_2$  is false):

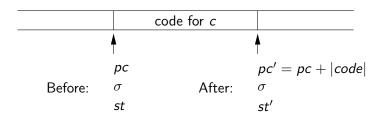

If cond = true (branch if  $b_1$  and  $b_2$  is true):

#### Compilation of commands

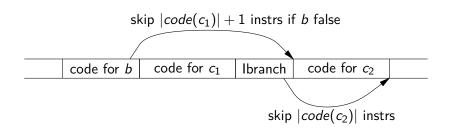

If the command c, started in initial state st, terminates in final state st',

(See function compile\_com in Compil.v)

#### The mysterious offsets

Code for IFB b THEN  $c_1$  ELSE  $c_2$  FI:

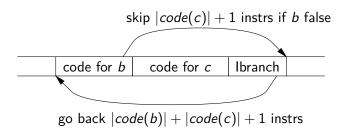

X. Leroy (Inria) Compiler verification DSSS 2017

32 / 226

#### The mysterious offsets

#### Code for WHILE b DO c END:

33 / 226

# Compiling IMP to virtual machine code

- Reminder: the IMP language
- 2 The IMP virtual machine
- 3 The compiler
- 4 Verifying the compiler: first results

### Compiler verification

We now have two ways to run a program:

- Interpret it using e.g. the ceval\_step function from ImpCEvalFun.v.
- Compile it, then run the generated virtual machine code.

Will we get the same results either way?

#### The compiler verification problem

Verify that a compiler is semantics-preserving:

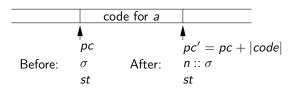

the generated code behaves as prescribed by the semantics of the source program.

 X. Leroy (Inria)
 Compiler verification
 DSSS 2017
 35 / 226

#### First verifications

Let's try to formalize and prove the intuitions we had when writing the compilation functions.

Intuition for arithmetic expressions: if a evaluates to n in store st,

A formal claim along these lines:

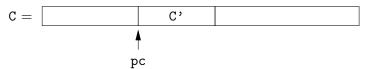

```
Lemma compile_aexp_correct:
  forall st a pc stk,
  star (transition (compile_aexp a))
      (0, stk, st)
      (length (compile_aexp a), aeval st a :: stk, st).
```

### Verifying the compilation of expressions

For this statement to be provable by induction over the structure of the expression *a*, we need to generalize it so that

- the start PC is not necessarily 0;
- the code compile\_aexp a appears as a fragment of a larger code C.

To this end, we define the predicate codeseq\_at C pc C' capturing the following situation:

## Verifying the compilation of expressions

```
Lemma compile_aexp_correct:
  forall C st a pc stk,
  codeseq_at C pc (compile_aexp a) ->
  star (transition C)
          (pc, stk, st)
          (pc + length (compile_aexp a), aeval st a :: stk, st).
```

Proof: a simple induction on the structure of a.

The base cases are trivial:

- a = n: a single Iconst transition.
- a = x: a single Ivar(x) transition.

#### An inductive case

Consider  $a = a_1 + a_2$  and assume

$$codeseq_at C pc (code(a_1) + +code(a_2) + +Iadd :: nil)$$

We have the following sequence of transitions:

$$(pc,\sigma,st)$$

$$\downarrow * \text{ ind. hyp. on } a_1$$

$$(pc + |code(a_1)|, \text{aeval } st \ a_1 :: \sigma, st)$$

$$\downarrow * \text{ ind. hyp. on } a_2$$

$$(pc + |code(a_1)| + |code(a_2)|, \text{aeval } st \ a_2 :: \text{aeval } st \ a_1 :: \sigma, st)$$

$$\downarrow \quad \text{Iadd transition}$$

$$(pc + |code(a_1)| + |code(a_2)| + 1, (\text{aeval } st \ a_1 + \text{aeval } st \ a_2) :: \sigma, st)$$

39 / 226

#### Historical note

As simple as this proof looks, it is of historical importance:

- First published proof of compiler correctness.
   (McCarthy and Painter, 1967).
- First mechanized proof of compiler correctness. (Milner and Weyrauch, 1972, using Stanford LCF).

John McCarthy James Painter<sup>1</sup>

# CORRECTNESS OF A COMPILER FOR ARITHMETIC EXPRESSIONS<sup>2</sup>

 Introduction. This paper contains a proof of the correctness of a simple compiling algorithm for compiling arithmetic expressions into machine language.

The definition of correctness, the formalism used to express the description of source language, object language and compiler, and the methods of proof are all intended to serve as prototypes for the more complicated task of proving the correctness of usable compilers. The ultimate goal, as outlined in references [1], [2], [3] and [4] is to make it possible to use a computer to check proofs that compilers are correct.

Mathematical Aspects of Computer Science, 1967

# Proving Compiler Correctness in a Mechanized Logic

R. Milner and R. Weyhrauch

Computer Science Department Stanford University

#### Abstract

We discuss the task of machine-checking the proof of a simple compiling algorithm. The proof-checking program is LCF, an implementation of a logic for computable functions due to Dana Scott, in which the abstract syntax and extensional semantics of programming languages can be naturally expressed. The source language in our example is a simple ALGOL-like language with assignments, conditionals, whiles and compound statements. The target language is an assembly language for a machine with a pushdown store. Algebraic methods are used to give structure to the proof, which is presented enly in outline. However, we present in full the expression-compiling part of the algorithm. More than half of the complete proof has been machine checked, and we anticipate no difficulty with the remainder. We discuss our experience in conducting the proof, which indicates that a large part of it may be automated to reduce the human contribution.

Machine Intelligence (7), 1972.

(Even the proof scripts look familiar!)

### Verifying the compilation of expressions

Similar approach for boolean expressions:

Proof: induction on the structure of b, plus copious case analysis.

# Verifying the compilation of commands

An induction on the structure of c fails because of the WHILE case. An induction on the derivation of c / st ==> st' works perfectly.

45 / 226

## Summary so far

Piecing the lemmas together, and defining

```
\texttt{compile\_program} \ c = \texttt{compile\_command} \ c \ + + \ \texttt{Ihalt} \ :: \ \texttt{nil}
```

we obtain a rather nice theorem:

```
Theorem compile_program_correct_terminating:
  forall c st st',
  c / st ==> st' ->
  mach_terminates (compile_program c) st st'.
```

But is this enough to conclude that our compiler is correct?

46 / 226

#### What could have we missed?

```
Theorem compile_program_correct_terminating:
  forall c st st',
  c / st ==> st' ->
  mach_terminates (compile_program c) st st'.
```

What if the generated VM code could terminate on a state other than st'? or loop? or go wrong?

What if the program c started in st diverges instead of terminating? What does the generated code do in this case?

Needed: more precise notions of semantic preservation + richer semantics (esp. for non-termination).

#### Part II

Notions of semantic preservation

## Comparing the behaviors of two programs

Consider two programs  $P_1$  and  $P_2$ , possibly in different languages.

(For example,  $P_1$  is an IMP command and  $P_2$  is virtual machine code generated by compiling  $P_1$ .)

The semantics of the two languages associate to  $P_1$ ,  $P_2$  sets  $\mathcal{B}(P_1)$ ,  $\mathcal{B}(P_2)$  of observable behaviors.

 $card(\mathcal{B}(P)) = 1$  if P is deterministic, and  $card(\mathcal{B}(P)) > 1$  if it is not.

#### Observable behaviors

For an IMP-like language:

```
observable \ behavior ::= terminates(st) \mid diverges \mid goeswrong
```

(Alternative: in the terminates case, observe not the full final state *st* but only the values of specific variables.)

For a functional language like lambda-calculus with constants:

 $observable \ behavior ::= terminates(v) \mid diverges \mid goeswrong$ 

where v is the value of the program.

#### Observable behaviors

For an imperative language with I/O: add a trace of input-output operations performed during execution.

```
x := 1; \quad x := 2; \approx x := 2; (trace: \epsilon)

print(1); print(2); \not\approx print(2); (trace: out(1).out(2))
```

# Bisimulation (observational equivalence)

$$\mathcal{B}(P_1)=\mathcal{B}(P_2)$$

The source and transformed programs are completely undistinguishable.

A very strong notion of semantic preservation.

Often too strong in practice ...

### Reducing non-determinism during compilation

Languages such as C leave evaluation order partially unspecified.

```
int x = 0;
int f(void) { x = x + 1; return x; }
int g(void) { x = x - 1; return x; }
```

The expression f() + g() can evaluate either

- to 1 if f() is evaluated first (returning 1), then g() (returning 0);
- to -1 if g() is evaluated first (returning -1), then f() (returning 0).

Every C compiler chooses one evaluation order at compile-time.

The compiled code therefore has fewer behaviors than the source program (1 instead of 2).

#### Reducing non-determinism during optimization

In a concurrent setting, classic optimizations often reduce non-determinism:

#### Original program:

```
a := x + 1; b := x + 1; run in parallel with x := 1;
```

Program after common subexpression elimination:

$$a := x + 1; b := a;$$
 run in parallel with  $x := 1;$ 

Assuming x = 0 initially, the final states for the original program are

$$(a,b) \in \{(1,1); (1,2); (2,2)\}$$

Those for the optimized program are

$$(a,b) \in \{(1,1); (2,2)\}$$

# Backward simulation (refinement)

$$\mathcal{B}(P_1)\supseteq\mathcal{B}(P_2)$$

Every possible possible behavior of  $P_2$  is justified as being one of the legal behaviors of  $P_1$ . However,  $P_2$  can have fewer behaviors (e.g. because some behaviors were eliminated during compilation).

Let Spec (a set of behaviors) be the functional specification of a program. A program P satisfies Spec iff  $\mathcal{B}(P) \subseteq Spec$ .

#### Lemma

If "backward simulation" holds and  $P_1$  satisfies Spec, then  $P_2$  satisfies Spec.

#### The pains of backward simulations

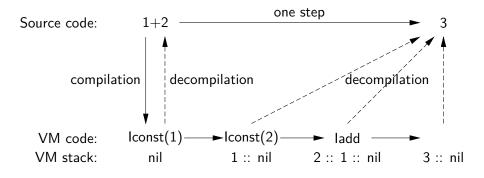

Backward simulation looks like "the" semantic preservation property we expect from a correct compiler.

It is however rather difficult to prove:

- We need to consider all steps that the compiled code can take, and trace them back to steps the source program can take.
- This is problematic if one source-level step is broken into several machine-level steps.

(E.g. x := a is one step in IMP, but several instructions in the VM.)

### General shape of a backward simulation proof

Intermediate VM code sequences like Iconst(2); Iadd or just Iadd do not correspond to the compilation of any source expression.

One solution: invent a decompilation function that is left-inverse of compilation. (Hard in general!)

X. Leroy (Inria) Compiler verification DSSS 2017 57 / 226

#### Forward simulations

Forward simulation property:

$$\mathcal{B}(P_1)\subseteq\mathcal{B}(P_2)$$

Significantly easier to prove than backward simulations. (For example, our first correctness proof for IMP compilation is of this form: termination of IMP program  $P_1$  implies termination of compiled VM code  $P_2$ .)

But is forward simulation a sufficient property? It shows that the compiled code  $P_2$  has all the good behaviors of  $P_1$ , but  $P_2$  could have other behaviors that are bad . . .

#### Determinism to the rescue!

#### Lemma

If  $P_2$  is deterministic (i.e.  $\mathcal{B}(P_2)$  is a singleton), then "forward simulation" implies "backward simulation" and therefore "bisimulation".

Trivial result: follows from  $\emptyset \subset X \subseteq \{y\} \Longrightarrow X = \{y\}$ .

# Should "going wrong" behaviors be preserved?

Compilers routinely "optimize away" going-wrong behaviors. For example:

```
x:=1\ /\ y;\ x:=42 optimized to x:=42 (goes wrong if y=0) (always terminates normally)
```

#### Justifications:

- We know that the program being compiled does not go wrong
  - because it was type-checked with a sound type system
  - or because it was formally verified.
- Or "it is the programmer's responsibility to avoid going-wrong behaviors, so the compiler can optimize under the assumption that there are none".

60 / 226

#### Simulations for safe programs

According to the ISO C standard, if one execution of the source program can go wrong ("invoke undefined behavior"), the code generated by the compiler can have any behavior whatsoever.

This corresponds to the weaker simulation properties below.

Safe backward simulation: goeswrong  $\notin \mathcal{B}(P_1) \implies \mathcal{B}(P_1) \supset \mathcal{B}(P_2)$ 

goeswrong  $\notin \mathcal{B}(P_1) \implies \mathcal{B}(P_1) \subseteq \mathcal{B}(P_2)$ Safe forward simulation:

## Should "going wrong" behaviors be preserved?

To minimize surprises and facilitate debugging, some C compilers (e.g. CompCert) preserve the behaviors of the source program up to the point where it goes wrong. Consider:

```
(1) printf("dividing by zero"); return 1/0;
```

- (2) printf("dividing by zero"); return 0
- (3) tmp = 1/0; printf("dividing by zero"); return tmp;

According to ISO C, (1) can be compiled like (2) and like (3) too. Compiling like (2) preserves the output up to the crash; (3) does not.

#### Simulations up to improvement

Define a pre-order "improves on" between behaviors. E.g.

- ISO C interpretation: goeswrong(t) is improved by any behavior.
- CompCert interpretation: goeswrong(t) is improved by any behavior whose trace of observables starts with t.

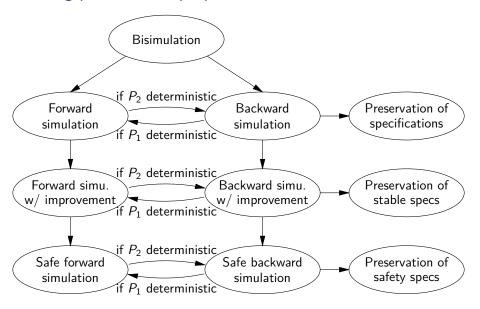

Backward simulation with improvement:

$$\forall b_2 \in \mathcal{B}(P_2), \exists b_1 \in \mathcal{B}(P_1), b_2 \text{ improves on } b_1$$

Forward simulation with improvement:

$$\forall b_1 \in \mathcal{B}(P_1), \exists b_2 \in \mathcal{B}(P_2), b_2 \text{ improves on } b_1$$

### Relating preservation properties

#### Back to the IMP $\rightarrow$ VM compiler

We have already proved half of a forward simulation result:

```
Theorem compile_program_correct_terminating:
  forall c st st',
  c / st ==> st' ->
  mach_terminates (compile_program c) st st'.
```

It remains to show the other half:

If command c diverges when started in state st, then the virtual machine, executing code compile\_program c from initial state st, makes infinitely many transitions.

(Note that IMP has no going-wrong behaviors.)

What we need: a formal characterization of divergence for IMP commands.

65 / 226

## Part III

## More on mechanized semantics

#### More on mechanized semantics

5 Reminder: big-step semantics for terminating programs

6 Small-step semantics

Small-step semantics with continuations

X. Leroy (Inria) Compiler verification DSSS 2017 67 / 226

#### Big-step semantics

A predicate  $c/s \Rightarrow s'$ , meaning "started in state s, command c terminates and the final state is s'".

$$\begin{array}{ll} \text{SKIP}/s \Rightarrow s & x := a/s \Rightarrow s[x \leftarrow \text{aeval } s \ a] \\ \\ \underline{c_1/s \Rightarrow s_1 \quad c_2/s_1 \Rightarrow s_2} \\ \hline c_1; c_2/s \Rightarrow s_2 & c_1/s \Rightarrow s' \text{ if beval } s \ b = \text{true} \\ \underline{c_2/s \Rightarrow s' \text{ if beval } s \ b = \text{false}} \\ \hline \text{IFB } b \text{ THEN } c_1 \text{ ELSE } c_2 \text{ FI}/s \Rightarrow s' \end{array}$$

$$\frac{\texttt{beval } s \ b = \texttt{false}}{\texttt{WHILE } b \ \texttt{DO } c \ \texttt{END}/s \Rightarrow s}$$

beval 
$$s$$
  $b= ext{true}$   $c/s \Rightarrow s_1$  WHILE  $b$  DO  $c$  END $/s_1 \Rightarrow s_2$ 

WHILE b DO c END/s  $\Rightarrow$  s<sub>2</sub>

# Pros and cons of big-step semantics

#### **Pros:**

- Follows naturally the structure of programs. (Gilles Kahn called it "natural semantics").
- Close connection with interpreters.
- Powerful induction principle (on the structure of derivations).
- Easy to extend with various structured constructs (functions and procedures, other forms of loops)

#### Cons:

- Fails to characterize diverging executions.
   (More precisely: no distinction between divergence and going wrong.)
- Concurrency, unstructured control (goto) nearly impossible to handle.

X. Leroy (Inria) Compiler verification DSSS 2017 69 / 226

# Big-step semantics and divergence

For IMP, a negative characterization of divergence:

$$c/s$$
 diverges  $\iff \neg(\exists s', \ c/s \Rightarrow s')$ 

In general (e.g. STLC), executions can also go wrong (in addition to terminating or diverging). Big-step semantics fails to distinguish between divergence and going wrong:

$$c/s$$
 diverges  $\lor c/s$  goes wrong  $\iff \neg(\exists s', c/s \Rightarrow s')$ 

Highly desirable: a positive characterization of divergence, distinguishing it from "going wrong".

#### More on mechanized semantics

5 Reminder: big-step semantics for terminating programs

6 Small-step semantics

Small-step semantics with continuations

X. Leroy (Inria) Compiler verification DSSS 2017 71/226

#### Small-step semantics

Also called "structured operational semantics".

Like  $\beta$ -reduction in the  $\lambda$ -calculus: view computations as sequences of reductions

$$M \stackrel{\beta}{\rightarrow} M_1 \stackrel{\beta}{\rightarrow} M_2 \stackrel{\beta}{\rightarrow} \dots$$

Each reduction  $M \to M'$  represents an elementary computation. M' represents the residual computations that remain to be done later.

## Small-step semantics for IMP

Reduction relation: 
$$c/s \rightarrow c'/s'$$
.

$$x := a/s \rightarrow \text{SKIP}/s[x \leftarrow \text{aeval } s \ a]$$

$$rac{c_1/s 
ightarrow c_1'/s'}{(c_1;c_2)/s 
ightarrow (c_1';c_2)/s'}$$
 (SKIP;  $c$ )/ $s 
ightarrow c/s$ 

beval s b = true

IFB 
$$b$$
 THEN  $c_1$  ELSE  $c_2$  FI $/s 
ightarrow c_1/s$ 

beval s b = false

IFB 
$$b$$
 THEN  $c_1$  ELSE  $c_2$  FI $/s 
ightarrow c_2/s$ 

WHILE b DO c END/s 
ightarrow IFB b THEN c; WHILE b DO c END ELSE SKIP/s

X. Leroy (Inria)

## Sequences of reductions

The behavior of a command c in an initial state s is obtained by forming sequences of reductions starting at c/s:

• Termination with final state s': finite sequence of reductions to SKIP.

$$c/s \rightarrow \cdots \rightarrow \texttt{SKIP}/s'$$

• Divergence: infinite sequence of reductions.

$$c/s \rightarrow c_1/s_1 \rightarrow \cdots \rightarrow c_n/s_n \rightarrow \cdots$$

 Going wrong: finite sequence of reductions to an irreducible command that is not SKIP.

$$(c,s) o \cdots o (c',s') 
ot o$$
 with  $c 
eq exttt{SKIP}$ 

# Equivalence small-step / big-step

A classic result:

$$c/s \Rightarrow s' \iff c/s \stackrel{*}{\rightarrow} \text{SKIP}/s'$$

(See Coq file Semantics.v.)

# Pros and cons of small-step semantics

#### **Pros:**

- Clean, unquestionable characterization of program behaviors (termination, divergence, going wrong).
- Extends even to unstructured constructs (goto, concurrency).
- De facto standard in the type systems community and in the concurrency community.

#### Cons:

- Does not follow the structure of programs; lack of a powerful induction principle.
- Syntax often needs to be extended with intermediate forms arising only during reductions.
- "Spontaneous generation" of terms.

# Reasoning with or without structure

Reasoning, big-step style: by pre- and post-conditions

- Single program: if  $c/s \Rightarrow s'$  and P s, then Q s'.
- Program transformation: if  $c/s \Rightarrow s'$  and T c  $c_1$  and P s  $s_1$ , there exists  $s_1'$  s.t.  $c_1/s_1 \Rightarrow s_1'$  and Q s'  $s_1'$ .

Proofs: by induction on a derivation of  $c/s \Rightarrow s'$ .

Reasoning, small-step style: by invariants and simulations.

- Single program: if  $c/s \to c'/s'$  and I(c,s) then I(c',s').
- Program transformation: a relation  $I(c, s)(c_1, s_1)$  is a (bi)-simulation for the transitions of the two programs.

Proofs: by case analysis on each transition.

#### Intermediate forms extending the syntax

Many programming constructs require unnatural extensions of the syntax of terms so that we can give reduction rules for these constructs.

**Example:** the break statement (as in C, Java, ...).

Commands: 
$$c := ... \mid BREAK \mid INLOOP c_1 c_2$$

Intuition: INLOOP  $c_1$   $c_2 \approx c_1$ ;  $c_2$  but with special treatment of BREAK arising out of  $c_1$ .

WHILE 
$$b$$
 DO  $c$  END/ $s \rightarrow c$  IFB  $b$  THEN INLOOP  $c$  (WHILE  $b$  DO  $c$  END) ELSE SKIP FI/ $s$ 

$$(\mathtt{BREAK}; c)/s \to \mathtt{BREAK}/s$$

(INLOOP SKIP 
$$c)/s o c/s$$

(INLOOP BREAK 
$$c$$
)/ $s o SKIP/s$ 

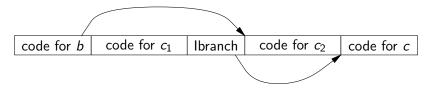

$$c_1/s o c_1'/s'$$

INLOOP 
$$c_1$$
  $c_2/s o$  INLOOP  $c_1'$   $c_2/s'$ 

# Spontaneous generation of terms

(IFB 
$$b$$
 THEN  $c_1$  ELSE  $c_2$  FI;  $c)/s \rightarrow (c_1; c)/s$ 

Compiled code for initial command:

This code does not contain the compiled code for  $c_1$ ; c, which is:

|--|

(Similar problem for WHILE b DO c END/s 
ightarrow IFB b THEN c; WHILE b DO c END ELSE SKIP/s.)

X. Leroy (Inria) Compiler verification DSSS 2017 79 / 226

#### More on mechanized semantics

5 Reminder: big-step semantics for terminating programs

6 Small-step semantics

Small-step semantics with continuations

#### Small-step semantics with continuations

A variant of standard small-step semantics that addresses issues #2 (no extensions of the syntax of commands) and #3 (no spontaneous generation of commands).

Idea: instead of rewriting whole commands:

$$c/s \rightarrow c'/s'$$

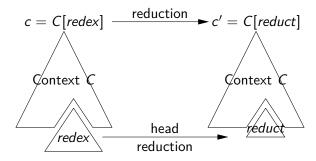

rewrite pairs of (subcommand under focus, remainder of command):

$$c/k/s \rightarrow c'/k'/s'$$

(Vaguely related to focusing in proof theory.)

## Standard small-step semantics

Rewrite whole commands, even though only a sub-command (the redex) changes.

82 / 226

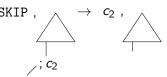

#### Focusing the small-step semantics

Rewrite pairs (subcommand, context in which it occurs).

$$x := a$$
 ,  $\rightarrow$  SKIP ,

The sub-command is not always the redex: add explicit focusing and resumption rules to move nodes between subcommand and context.

Focusing on the left of a sequence

Resuming a sequence

# Representing contexts "upside-down"

```
Inductive ctx :=
                                    Inductive cont :=
  | CThole: ctx
                                   | Kstop: cont
  | CTseq: com -> ctx -> ctx.
                                   | Kseq: com -> cont -> cont.
                                                 Kstop
                                             Kseq
CTseq (CTseq CThole x) y) z
                                      Kseq x (Kseq y (Kseq z Kstop))
Upside-down context \approx continuation.
("Eventually, do x, then do y, then do z, then stop.")
```

#### Transition rules

$$x := a/k/s \quad \rightarrow \quad \text{SKIP}/k/s[x \leftarrow \text{aeval } s \ a] \\ (c_1; c_2)/k/s \quad \rightarrow \quad c_1/\text{Kseq } c_2 \ k/s \\ \text{IFB } b \text{ THEN } c_1 \text{ ELSE } c_2/k/s \quad \rightarrow \quad c_1/k/s \qquad \text{if beval } s \ b = \text{true} \\ \text{IFB } b \text{ THEN } c_1 \text{ ELSE } c_2/k/s \quad \rightarrow \quad c_2/k/s \qquad \text{if beval } s \ b = \text{false} \\ \text{WHILE } b \text{ DO } c \text{ END}/k/s \quad \rightarrow \quad c/\text{Kseq (WHILE } b \text{ DO } c \text{ END) } k/s \\ \text{if beval } s \ b = \text{true} \\ \text{WHILE } b \text{ DO } c \text{ END}/k/s \quad \rightarrow \quad \text{SKIP}/c/k \qquad \text{if beval } s \ b = \text{false} \\ \text{SKIP/Kseq } c \ k/s \quad \rightarrow \quad c/k/s \\ \end{cases}$$

Note: no spontaneous generation of fresh commands.

X. Leroy (Inria) Compiler verification DSSS 2017 85 / 226

# Enriching the language

Let's add a break statement. We need a new form of continuations for loops, but no ad-hoc extension to the syntax of commands.

```
Commands: c := ... \mid BREAK
```

Continuations:  $k ::= Kstop \mid Kseq c \mid Kwhile \mid b \mid c \mid k$ 

New or modified rules:

WHILE 
$$b$$
 DO  $c$  END/ $k/s$   $\rightarrow$   $c/{\tt Kwhile}$   $b$   $c$   $k/s$  if beval  $s$   $b$  = true SKIP/Kwhile  $b$   $c$   $k/s$   $\rightarrow$  WHILE  $b$  DO  $c$  END/ $k/s$  BREAK/Kseq  $c$   $k/s$   $\rightarrow$  BREAK/ $k/s$  BREAK/Kwhile  $b$   $c$   $k/s$   $\rightarrow$  SKIP/ $k/s$ 

(Exercise: what about continue?)

## Equivalence with the other semantics

$$c/\texttt{Kstop}/s \overset{*}{\to} \texttt{SKIP}/\texttt{Kstop}/s' \quad \text{iff} \quad c/s \Rightarrow s' \quad \text{iff} \quad c/s \overset{*}{\to} \texttt{SKIP}/s'$$
 
$$c/k/s \to \infty \quad \text{iff} \quad c/s \to \infty$$

(See Coq file Semantics.v)

#### Part IV

# Compiling IMP to virtual machine code, continued

## Finishing the proof of forward simulation

One half already proved: the terminating case.

```
Theorem compile program correct terminating:
  forall c st st',
  c / st \\ st' ->
 mach terminates (compile program c) st st'.
```

```
One half to go: the diverging case.
(If c/st diverges, then mach diverges (compile program c) st.)
```

89 / 226

## Forward simulations, small-step style

Show that every transition in the execution of the source program

- is simulated by some transitions in the compiled program
- while preserving a relation between the configurations of the two programs.

#### Lock-step simulation

Every transition of the source is simulated by exactly one transition in the compiled code.

(Black = hypotheses; red = conclusions.)

#### Lock-step simulation

Further show that initial configurations are related:

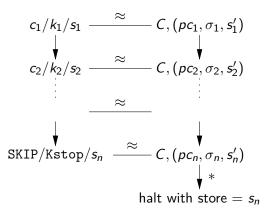

$$c/\texttt{Kstop}/s \approx (C, (0, nil, s)) \text{ with } C = \texttt{compile\_program}(c)$$

Further show that final configurations are quasi-related:

$$\begin{aligned} \mathtt{SKIP}/\mathtt{Kstop}/s &\approx (C, \mathit{mst}) \\ &\implies (C, \mathit{mst}) \overset{*}{\to} (C, (\mathit{pc}, \mathit{nil}, s)) \land C(\mathit{pc}) = \mathtt{Ihalt} \end{aligned}$$

#### Lock-step simulation

Forward simulation follows easily:

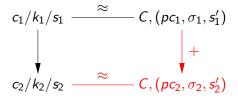

(Likewise if  $c_1/k_1/s_1$  reduces infinitely.)

## "Plus" simulation diagrams

In some cases, each transition in the source program is simulated by one or several transitions in the compiled code.

(Example: compiled code for x := a consists of several instructions.)

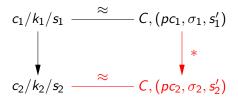

Forward simulation still holds.

# "Star" simulation diagrams (incorrect)

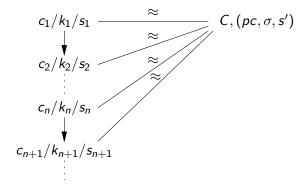

In other cases, each transition in the source program is simulated by zero, one or several transitions in the compiled code.

(Example: source reduction (SKIP;  $c)/s \rightarrow c/s$  makes zero transitions in the machine code.)

Forward simulation is not guaranteed: terminating executions are preserved; but diverging executions may not be preserved.

# The "infinite stuttering" problem

The source program diverges but the compiled code can terminate, normally or by going wrong.

 X. Leroy (Inria)
 Compiler verification
 DSSS 2017
 96 / 226

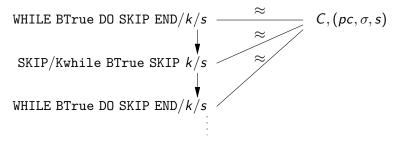

# An incorrect optimization that exhibits infinite stuttering

Add special cases to compile\_com so that the following trivially infinite loop gets compiled to no instructions at all:

compile\_com (WHILE BTrue DO SKIP END) = nil

## Infinite stuttering

Adding special cases to the  $\approx$  relation, we can prove the following naive "star" simulation diagram:

Conclusion: a naive "star" simulation diagram does not prove that a compiler is correct.

98 / 226

# "Star" simulation diagrams (corrected)

Find a measure M(c, k): nat over source terms that decreases strictly when a stuttering step is taken. Then show:

$$c_{1}/k_{1}/s_{1} \xrightarrow{\approx} C, (pc_{1}, \sigma_{1}, s'_{1}) \qquad c_{1}/k_{1}/s_{1} \xrightarrow{\approx} C, (pc_{1}, \sigma_{1}, s'_{1}) \\ \downarrow \qquad \qquad \downarrow \qquad \qquad \downarrow \qquad \qquad \downarrow \\ c_{2}/k_{2}/s_{2} \xrightarrow{\approx} C, (pc_{2}, \sigma_{2}, s'_{2}) \qquad c_{2}/k_{2}/s_{2} \text{ and } M(c_{2}, k_{2}) < M(c_{1}, k_{1})$$

Forward simulation, terminating case: OK (as before).

Forward simulation, diverging case: OK.

(If c/k/s diverges, it must perform infinitely many non-stuttering steps, so the machine executes infinitely many transitions.)

 X. Leroy (Inria)
 Compiler verification
 DSSS 2017
 99 / 226

## Application to the IMP $\rightarrow$ VM compiler

Let's try to prove a "star" simulation diagram for our compiler.

#### Two difficulties:

- Rule out infinite stuttering.
- ② Match the current command-continuation c, k (which changes during reductions) with the compiled code C (which is fixed throughout execution).

#### Anti-stuttering measure

Stuttering reduction = no machine instruction executed. These include:

$$(c_1;c_2)/k/s \ \to \ c_1/{\tt Kseq} \ c_2 \ k/s$$
 
$${\tt SKIP/Kseq} \ c \ k/s \ \to \ c/k/s$$
 
$$({\tt IFB} \ {\tt BTrue} \ {\tt THEN} \ c_1 \ {\tt ELSE} \ c_2)/k/s \ \to \ c_1/k/s$$
 
$$({\tt WHILE} \ {\tt BTrue} \ {\tt DO} \ c \ {\tt END})/k/s \ \to \ c/{\tt Kwhile} \ {\tt BTrue} \ c \ k/s$$

No measure M on the command c can rule out stuttering: for M to decrease in the second case above, we should have

$$M(SKIP) > M(c)$$
 for all commands  $c$ , including  $c = SKIP$ 

 $\rightarrow$  We must measure (c, k) pairs.

## Anti-stuttering measure

After some trial and error, an appropriate measure is:

$$M(c, k) = size(c) + \sum_{c' \text{ appears in } k} size(c')$$

In other words, every constructor of com counts for 1, and every constructor of cont counts for 0.

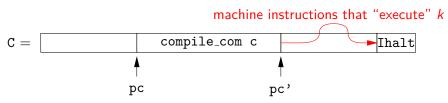

$$M((c_1;c_2),k) = M(c_1, ext{Kseq}\ c_2\ k) + 1 \ M( ext{SKIP}, ext{Kseq}\ c\ k) = M(c,k) + 1 \ M( ext{IFB}\ b\ ext{THEN}\ c_1\ ext{ELSE}\ c_2\ ext{FI},k) \geq M(c_1,k) + 1 \ M( ext{WHILE}\ b\ ext{DO}\ c\ ext{END},k) = M(c, ext{Kwhile}\ b\ c\ k) + 1$$

# Relating commands and continuations with compiled code

In the big-step proof: codeseq\_at C pc (compile\_com c).

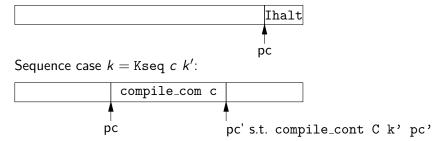

In a proof based on the small-step continuation semantics: we must also relate continuations k with the compiled code:

## Relating continuations with compiled code

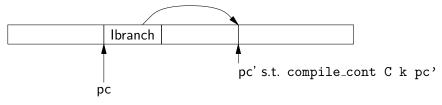

A predicate compile\_cont C k pc, meaning "there exists a code path in C from pc to a Ihalt instruction that executes the pending computations described by k".

Base case k = Kstop:

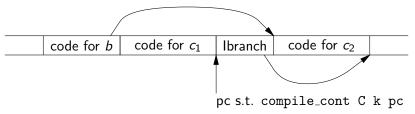

### Relating continuations with compiled code

A "non-structural" case allowing us to insert branches at will:

Useful to handle continuations arising out of IFB b THEN  $c_1$ ELSE  $c_2$ :

#### The simulation invariant

A source-level configuration (c, k, s) is related to a machine configuration  $C, (pc, \sigma, s')$  iff:

- the memory states are identical: s' = s
- the stack is empty:  $\sigma = \epsilon$
- C contains the compiled code for command c starting at pc
- C contains compiled code matching continuation k starting at pc + |code(c)|.

# The simulation diagram

$$c_{1}/k_{1}/s_{1} \xrightarrow{C \vdash c_{1}/k_{1}/s_{1} \approx (pc_{1}, \epsilon, s_{1})} (pc_{1}, \epsilon, s_{1}')$$

$$\downarrow \qquad \qquad \downarrow \qquad \qquad \qquad \qquad \downarrow \qquad \qquad \qquad \qquad \downarrow \qquad \qquad \qquad \downarrow \qquad \qquad \qquad \qquad \qquad \downarrow \qquad \qquad \qquad \qquad \qquad \downarrow \qquad \qquad \qquad \qquad \qquad \downarrow$$

Proof: by case analysis on the source transition on the left.

X. Leroy (Inria) Compiler verification DSSS 2017 107 / 226

# Wrapping up

As a corollary of this simulation diagram, we obtain both:

- An alternate proof of compiler correctness for terminating programs: if  $c/\text{Kstop}/s \stackrel{*}{\to} \text{SKIP}/\text{Kstop}/s'$  then mach\_terminates (compile\_program c) s s'
- A proof of compiler correctness for diverging programs:
   if c/Kstop/s reduces infinitely,
   then mach\_diverges (compile\_program c) s

Mission complete!

#### Part V

Optimizations based on liveness analysis

### Compiler optimizations

Automatically transform the programmer-supplied code into equivalent code that

- Runs faster
  - Removes redundant or useless computations.
  - ▶ Use cheaper computations (e.g.  $x * 5 \rightarrow (x << 2) + x$ )
  - Exhibits more parallelism (instruction-level, thread-level).
- Is smaller
   (For cheap embedded systems.)
- Consumes less energy (For battery-powered systems.)
- Is more resistant to attacks
   (For smart cards and other secure systems.)

Dozens of compiler optimizations are known, each targeting a particular class of inefficiencies.

### Compiler optimization and static analysis

Some optimizations are unconditionally valid, e.g.:

Most others apply only if some conditions are met:

 $\rightarrow$  need a static analysis prior to the actual code transformation.

### Static analysis

Determine some properties of all concrete executions of a program.

Often, these are properties of the values of variables at a given program point:

$$x = n$$
  $x \in [n, m]$   $x = expr$   $a.x + b.y \le n$ 

#### Requirements:

- The inputs to the program are unknown.
- The analysis must terminate.
- The analysis must run in reasonable time and space.

# Running example: dead code elimination via liveness analysis

Remove assignments x := e, turning them into skip, whenever the variable x is never used later in the program execution.

#### Example

```
Consider: x := 1; y := y + 1; x := 2
```

The assignment x := 1 can always be eliminated since x is not used before being redefined by x := 2.

Builds on a static analysis called liveness analysis.

# Optimizations based on liveness analysis

8 Liveness analysis

Dead code elimination

10 Advanced topic: register allocation

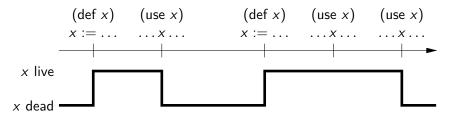

#### Notions of liveness

A variable is dead at a program point if its value is not used later in any execution of the program:

- either the variable is not mentioned again before going out of scope
- or it is always redefined before further use.

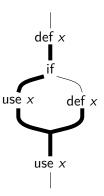

A variable is live if it is not dead.

Easy to compute for straight-line programs (sequences of assignments):

#### Notions of liveness

Liveness information is more delicate to compute in the presence of conditionals and loops:

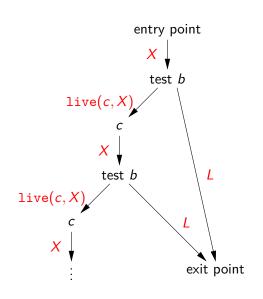

Conservatively over-approximate liveness, assuming all if conditionals can be true or false, and all while loops are taken 0 or several times.

### Liveness equations

Given a set L of variables live "after" a command c, write live(c, L) for the set of variables live "before" the command.

$$\label{eq:live} \begin{array}{rcl} \text{live}(\text{SKIP},L) &=& L \\ \\ \text{live}(x:=a,\ L) &=& \begin{cases} (L\setminus\{x\})\cup FV(a) & \text{if } x\in L; \\ L & \text{if } x\notin L. \end{cases} \\ \\ \text{live}((c_1;c_2),\ L) &=& \text{live}(c_1,\text{live}(c_2,L)) \\ \\ \text{live}((\text{IFB } b\text{ THEN } c_1\text{ ELSE } c_2),\ L) &=& FV(b)\cup \text{live}(c_1,L)\cup \text{live}(c_2,L) \\ \\ \text{live}((\text{WHILE } b\text{ DO } c\text{ END}),\ L) &=& X \text{ such that } \\ && X\supseteq L\cup FV(b)\cup \text{live}(c,X) \end{cases}$$

### Liveness for loops

We must have:

- $FV(b) \subseteq X$  (evaluation of b)
- $L \subseteq X$  (if b is false)
- live $(c, X) \subseteq X$ (if b is true and c is executed)

# Fixpoints, a.k.a "the recurring problem"

Consider  $F = \lambda X$ .  $L \cup FV(b) \cup \text{live}(c, X)$ .

To analyze while loops, we need to compute a pre-fixpoint of F, i.e. an X such that  $F(X) \subseteq X$ .

For maximal precision, X would preferably be the smallest fixpoint F(X) = X; but for soundness, any pre-fixpoint suffices.

# The mathematician's approach to fixpoints

Let  $A, \leq$  be a partially ordered type. Consider  $F: A \rightarrow A$ .

#### Theorem (Knaster-Tarski)

The sequence

$$\perp$$
,  $F(\perp)$ ,  $F(F(\perp))$ , ...,  $F^n(\perp)$ ,...

converges to the smallest fixpoint of F, provided that

- F is increasing:  $x \le y \Rightarrow F(x) \le F(y)$ .
- ⊥ is a smallest element.
- All strictly ascending chains  $x_0 < x_1 < \ldots < x_n$  are finite.

This provides an effective way to compute fixpoints. (See Coq file Fixpoint.v).

#### Problems with Knaster-Tarski

- Formalizing and exploiting the ascending chain property
   → well-founded orderings and Noetherian induction.
- ② In our case (liveness analysis), the ordering  $\subset$  has infinite ascending chains:  $\emptyset \subset \{x_1\} \subset \{x_1, x_2\} \subset \cdots$ Need to restrict ourselves to subsets of a given, finite universe of variables (= all variables free in the program).
  - $\rightarrow$  dependent types.

Time for plan B...

# The engineer's approach to fixpoints

$$F = \lambda X. \ L \cup FV(b) \cup live(c, X)$$

- Compute  $F(\emptyset), F(F(\emptyset)), \dots, F^N(\emptyset)$  up to some fixed N.
- Stop as soon as a pre-fixpoint is found  $(F^{i+1}(\emptyset) \subseteq F^i(\emptyset))$ .
- Otherwise, return a safe over-approximation (in our case,  $a \cup FV$ (while b do c done)).

A compromise between analysis time and analysis precision.

(Coq implementation: see file Deadcode.v)

# Optimizations based on liveness analysis

8 Liveness analysis

Dead code elimination

10 Advanced topic: register allocation

#### Dead code elimination

The program transformation eliminates assignments to dead variables:

x := a becomes SKIP if x is not live "after" the assignment

Presented as a function dce :  $com \rightarrow VS.t \rightarrow com$  taking the set of variables live "after" as second parameter and maintaining it during its traversal of the command.

(Implementation & examples in file Deadcode.v)

### The semantic meaning of liveness

What does it mean, semantically, for a variable x to be live at some program point?

Hmmm...

### The semantic meaning of liveness

What does it mean, semantically, for a variable x to be live at some program point?

Hmmm...

What does it mean, semantically, for a variable x to be dead at some program point?

That its precise value has no impact on the rest of the program execution!

### Liveness as an information flow property

Consider two executions of the same command c in different initial states:

$$c/s_1 \Rightarrow s_2$$
  
 $c/s'_1 \Rightarrow s'_2$ 

Assume that the initial states agree on the variables live(c, L) that are live "before" c:

$$\forall x \in \text{live}(c, L), \quad s_1(x) = s_1'(x)$$

Then, the two executions terminate on final states that agree on the variables L live "after" c:

$$\forall x \in L, \quad s_2(x) = s_2'(x)$$

The proof of semantic preservation for dead-code elimination follows this pattern, relating executions of c and dce c L instead.

X. Leroy (Inria) Compiler verification DSSS 2017 126 / 226

### Agreement and its properties

```
Definition agree (L: VS.t) (s1 s2: state) : Prop := forall x, VS.In x L \rightarrow s1 x = s2 x.
```

Agreement is monotonic w.r.t. the set of variables L:

```
Lemma agree_mon:
  forall L L' s1 s2,
  agree L' s1 s2 -> VS.Subset L L' -> agree L s1 s2.
```

Expressions evaluate identically in states that agree on their free variables:

```
Lemma aeval_agree:
  forall L s1 s2, agree L s1 s2 ->
  forall a, VS.Subset (fv_aexp a) L -> aeval s1 a = aeval s2 a.
Lemma beval_agree:
  forall L s1 s2, agree L s1 s2 ->
  forall b, VS.Subset (fv_bexp b) L -> beval s1 b = beval s2 b.
```

### Agreement and its properties

Agreement is preserved by parallel assignment to a variable:

```
Lemma agree_update_live:
  forall s1 s2 L x v,
  agree (VS.remove x L) s1 s2 ->
  agree L (update s1 x v) (update s2 x v).
```

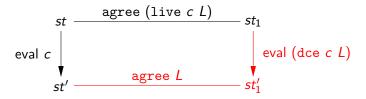

Agreement is also preserved by unilateral assignment to a variable that is dead "after":

```
Lemma agree_update_dead:
  forall s1 s2 L x v,
  agree L s1 s2 -> ~VS.In x L ->
  agree L (update s1 x v) s2.
```

#### Forward simulation for dead code elimination

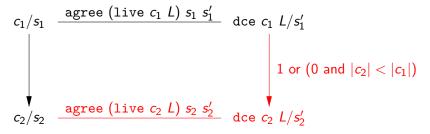

For terminating source programs:

```
Theorem dce_correct_terminating:
  forall st c st', c / st \\ st' ->
  forall L st1,
  agree (live c L) st st1 ->
  exists st1', dce c L / st1 \\ st1' /\ agree L st' st1'.
(Proof: an induction on the derivation of c / st ==> st'.)
```

#### Forward simulation for dead code elimination

Exercise: extend the result to diverging programs by proving a simulation diagram for the transitions of the small-step semantics of IMP (no need for continuations):

# Optimizations based on liveness analysis

8 Liveness analysis

Dead code elimination

10 Advanced topic: register allocation

### The register allocation problem

Place the variables used by the program (in unbounded number) into:

- either hardware registers
   (very fast access, but available in small quantity)
- or memory locations (generally allocated on the stack)
   (available in unbounded quantity, but slower access)

Try to maximize the use of hardware registers.

A crucial step for the generation of efficient machine code.

# Approaches to register allocation

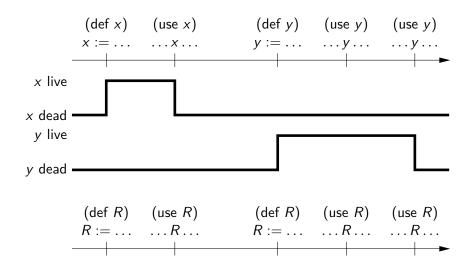

#### Naive approach (injective allocation):

- ullet Assign the N most used variables to the N available registers.
- Assign the remaining variables to memory locations.

#### Optimized approach (non-injective allocation):

 Notice that two variables can share a register as long as they are not simultaneously live.

## Example of register sharing

## Register allocation for IMP

#### Properly done:

- Break complex expressions by introducing temporaries. (E.g. x = (a + b) \* y becomes tmp = a + b; x = tmp \* y.)
- ② Translate IMP to a variant IMP' that uses registers ∪ memory locations instead of variables.

#### Simplified as follows in this lecture:

- 1 Do not break expressions.
- 2 Translate from IMP to IMP, by renaming identifiers. (Convention: low-numbered identifiers  $\approx$  hardware registers.)

## The program transformation

Assume given a "register assignment"  $f : id \rightarrow id$ .

The program transformation consists of:

- Renaming variables: all occurrences of x become f(x).
- Dead code elimination:

$$x := a \longrightarrow SKIP$$
 if x is dead "after"

Coalescing:

$$x ::= y \longrightarrow SKIP \text{ if } f x = f y$$

### Correctness conditions on the register assignment

Clearly, not all register assignments f preserve semantics.

Example: assume f x = f y = f z = R

```
x ::= 1; R ::= 1; y ::= 2; R ::= 2; R ::= R + R;
```

Computes 4 instead of 3 ...

What are sufficient conditions over *f*? Let's discover them by reworking the proof of dead code elimination.

#### Agreement, revisited

```
Definition agree (L: VS.t) (s1 s2: state) : Prop := forall x, VS.In x L \rightarrow s1 x = s2 (f x).
```

An expression and its renaming evaluate identically in states that agree on their free variables:

```
Lemma aeval_agree:
   forall L s1 s2, agree L s1 s2 ->
   forall a, VS.Subset (fv_aexp a) L ->
   aeval s1 a = aeval s2 (rename_aexp a).

Lemma beval_agree:
   forall L s1 s2, agree L s1 s2 ->
   forall b, VS.Subset (fv_bexp b) L ->
   beval s1 b = beval s2 (rename_bexp b).
```

#### Agreement, revisited

As before, agreement is monotonic w.r.t. the set of variables L:

```
Lemma agree_mon:
  forall L L' s1 s2,
  agree L' s1 s2 -> VS.Subset L L' -> agree L s1 s2.
```

As before, agreement is preserved by unilateral assignment to a variable that is dead "after":

```
Lemma agree_update_dead:
  forall s1 s2 L x v,
  agree L s1 s2 -> ~VS.In x L ->
  agree L (update s1 x v) s2.
```

#### Agreement, revisited

Agreement is preserved by parallel assignment to a variable x and its renaming f(x), but only if f satisfies a non-interference condition (in red below):

```
Lemma agree_update_live:
  forall s1 s2 L x v,
  agree (VS.remove x L) s1 s2 ->
   (forall z, VS.In z L -> z <> x -> f z <> f x) ->
  agree L (update s1 x v) (update s2 (f x) v).
```

```
Counter-example: assume f x = f y = R. agree \{y\} (x = 0, y = 0) (R = 0) holds, but agree \{x; y\} (x = 1, y = 0) (R = 1) does not.
```

### A special case for moves

Consider a variable-to-variable copy x := y.

In this case, the value v assigned to x is not arbitrary, but known to be  ${\tt s1}\ y$ . We can, therefore, weaken the non-interference criterion:

```
Lemma agree_update_move:
  forall s1 s2 L x y,
  agree (VS.union (VS.remove x L) (VS.singleton y)) s1 s2 ->
  (forall z, VS.In z L -> z <> x -> z <> y -> f z <> f x) ->
  agree L (update s1 x (s1 y)) (update s2 (f x) (s2 (f y))).
```

This makes it possible to assign x and y to the same location, even if x and y are simultaneously live.

## The interference graph

The various non-interference constraints  $f \ x \neq f \ y$  can be represented as an interference graph:

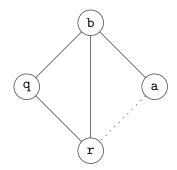

- Nodes = program variables.
- Undirected edge between x and y =
   x and y cannot be assigned the same location.

Chaitin's algorithm to construct this graph:

- For each move x := y, add edges between x and every variable z live "after" except x and y.
- For each other assignment x := a, add edges between x and every variable z live "after" except x.

## Example of an interference graph

```
r := a;
q := 0;
WHILE b <= r DO
r := r - b;
q := q + 1
END
```

(Full edge = interference; dotted edge = preference.)

# Register allocation as a graph coloring problem

(G. Chaitin, 1981; P. Briggs, 1987)

Color the interference graph, assigning a register or memory location to every node;

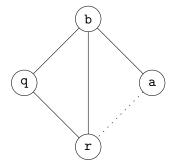

under the constraint that the two ends of an interference edge have different colors;

with the objective to

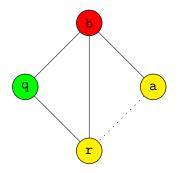

- minimize the number (or total weight) of nodes that are colored by a memory location
- maximize the number of preference edges whose ends have the same color.

(A NP-complete problem in general, but good linear-time heuristics exist.)

# Example of coloring

## Example of coloring

```
yellow := yellow;
green := 0;
WHILE red <= yellow DO
  yellow := yellow - red;
  green := green + 1
END</pre>
```

### What needs to be proved in Coq?

#### Full compiler proof:

formalize and prove correct a good graph coloring heuristic.

George and Appel's Iterated Register Coalescing  $\approx$  6 000 lines of Coq.

#### Validation a posteriori:

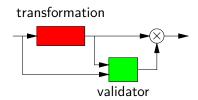

invoke an external, unproven oracle to compute a candidate allocation; check that it satisfies the non-interference conditions; abort compilation if the checker says false.

### The verified transformation-verified validation spectrum

#### Verified transformation

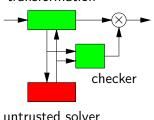

#### Verified translation validation

#### External solver with verified validation

transformation

= formally verified
= not verified

X. Leroy (Inria)

### Validating candidate allocations in Coq

It is easy to write a Coq boolean-valued function

```
correct_allocation: (id -> id) -> com -> VS.t -> bool
```

that returns true only if the expected non-interference properties are satisfied.

(See file Regalloc.v.)

#### Semantic preservation

The proofs of forward simulation that we did for dead code elimination then extend easily, under the assumption that correct\_allocation returns true:

```
Theorem transf_correct_terminating:
  forall st c st', c / st
st' ->
  forall L st1, agree (live c L) st st1 ->
  correct_allocation c L = true ->
  exists st1', transf_com c L / st1
st1' / agree L st' st1'.
```

#### Part VI

Compiler verification in the large: CompCert

## Compiler verification in the large: CompCert

- The CompCert project
- Tower of Babel: the languages of CompCert
- 13 The CompCert memory model
- Observables, non-determinism, and semantic preservation
- 15 Concluding remarks

## The CompCert project

```
(X.Leroy, S.Blazy, et al — http://compcert.inria.fr/)
```

Develop and prove correct a realistic compiler, usable for critical embedded software.

- Source language: a subset of C.
- Target language: PowerPC, ARM and x86 assembly.
- Generates reasonably compact and fast code
   ⇒ some optimizations.

This is "software-proof codesign": the compiler and its proof are written from scratch; not trying to prove an existing compiler.

Uses Coq to mechanize the proof of semantic preservation and also to implement most of the compiler.

## The subset of C supported

#### Supported:

- Types: integers, floats, arrays, pointers, struct, union.
- Operators: arithmetic, pointer arithmetic.
- Control: if/then/else, loops, simple switch, goto.
- Functions, recursive functions, function pointers.

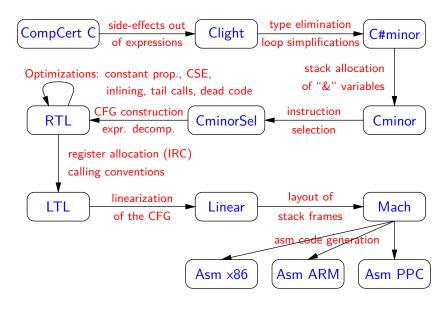

#### Not supported:

- The long double type.
- Unstructured switch, longjmp/setjmp.

#### Supported via de-sugaring (not proved!):

- Block-scoped variables.
- Returning struct and union by value from functions
- Bit-fields.
- Variable-arity functions.

### The formally verified part of the compiler

## Formally verified using Coq

The correctness proof (semantic preservation) for the compiler is entirely machine-checked, using the Coq proof assistant.

A fairly large proof: 120 000 lines, 8 person.years, low automation.

## Programmed (mostly) in Coq

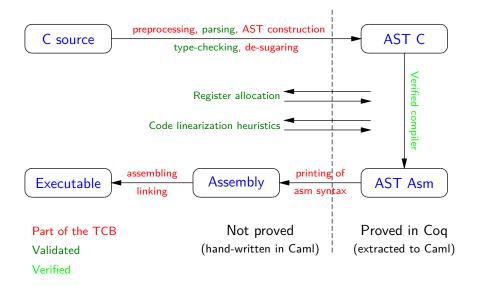

All the verified parts of the compiler are programmed directly in Coq's specification language, using pure functional style.

- Monads to handle errors and mutable state.
- Purely functional data structures.

Coq's extraction mechanism produces executable Caml code from these specifications.

Claim: purely functional programming is the shortest path to writing and proving a program.

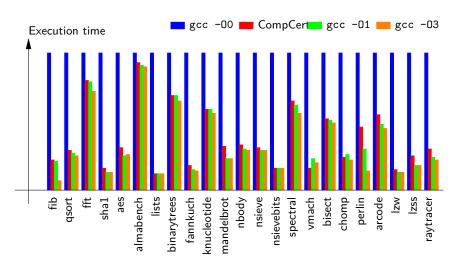

## The whole Compcert compiler

X. Leroy (Inria) Compiler verification DSSS 2017 157 / 226

### Performance of generated code

(On a Power 7 processor)

### A tangible increase in quality

The striking thing about our CompCert results is that the middleend bugs we found in all other compilers are absent. As of early 2011, the under-development version of CompCert is the only compiler we have tested for which Csmith cannot find wrong-code errors. This is not for lack of trying: we have devoted about six CPU-years to the task. The apparent unbreakability of CompCert supports a strong argument that developing compiler optimizations within a proof framework, where safety checks are explicit and machine-checked, has tangible benefits for compiler users.

X. Yang, Y. Chen, E. Eide, J. Regehr, PLDI 2011

159 / 226

## **Availability**

http://compcert.inria.fr/

Source distribution, documentation, papers, commented Coq.

For non-commercial use (evaluation, research, teaching).

AbsInt (http://absint.com) sells a commercial version of CompCert with technical support.

### The languages of CompCert

Source language: CompCert C

Target language: Asm (three variants: ARM, PowerPC, x86)

8 intermediate languages that bridge the gap.

Some intermediate languages are reused in other projects:

- Clight: VST program logic; Velus Lustre compiler
- C#minor: Verasco static analyzer by abstract interpretation
- Cminor: MiniML compiler, GHC Core compiler.

## Machine (in-)dependence

```
CompCert C
                Independent of the target processor
   C#minor
     Cminor
  CminorSel
                Parameterized by the target processor
               - Operations, conditions, addressing modes (module Op)
               - Machine registers (Machregs)
      Linear
               - Calling conventions (Conventions0)
      Mach
               Specific to the target processor
```

### Representing control flow

```
Expressions with side-effects; statements (structured, goto)
    Clight
C#minor
Cminor
              Pure expressions; statements (structured, goto)
CminorSel

              Control-Flow Graph of basic blocks
              List of instructions w/ labels and jumps
    Linear
              List of instructions indexed by PC
```

## Control-flow graphs

```
double average(int * tbl, int size)
   double s = 0.0;
   int i;
   for (i = 0; i < size; i++)
       s = s + tbl[i];
   return s;
                              s = 0.0
                                i = 0
                          if (i \ge size)
      d = float(size)
                                                a = i << 2
         e = s /_f d
                                               = load(tbl+a)
          return(e)
                                               c = float(b)
                                                s = s +_f c
                                                i = i + 1
```

#### Representing local variables

(Global variables and dynamically-allocated memory: unchanged throughout compilation.)

```
CompCert C Local addressable variables
               Local addressable variables + temporaries (local, non-a var)
    Cminor
 CminorSel Stack frame + temporaries
               {\sf Stack\ frame\ +\ locations\ (machine\ registers\ or\ stack\ slots)}
             Stack frame + machine registers
      Mach
```

### A look at abstract syntax trees

#### Asm

Note: flat structure, many instructions, some pseudo.

#### **RTL**

Note: few instructions, parameterization by operations/conditions/addressing modes of the target.

#### Clight

Note: expressions are pure, assignments and function calls are statements.

#### CompCert C

Note: complex expressions including assignments (several forms) and function calls.

## Programs and compilation units

Common to all languages, a compilation unit is a name for a main entry point plus a list of (name, definition/declaration):

- Internal function definition (language-dependent)
- External function declaration
- Variable definition/declaration, including size and initialization data language-dependent information (e.g. the C type)

See module AST.

Module Linking defines a general framework for linking compilation units together, connecting identically-named definitions of one unit with external declarations of another unit [KKH $^+$ 16].

# Styles of semantics used (as a function of time)

	Clight Cminor	RTL Mach	Asm
1st gen.	big-step	"mixed-step" (b.s. for calls, (s.s. otherwise)	small-step
2nd gen. (+ divergence)	big-step (coinductive)	small-step (w/ call stacks)	small-step
3rd gen. (+ goto & tailcalls)	small-step (w/ continuations)	small-step (w/ call stacks)	small-step

## CompCert's semantics, today

All languages use Labeled Transition Systems to describe their operational semantics in small-step style.

$$genv \vdash state_1 \xrightarrow{t} state_2$$

- genv: global environment, maps global identifiers (functions, variables) to memory addresses, and those addresses to the definitions/declarations. (See module Globalenvs.)
- state<sub>1</sub>, state<sub>2</sub>: execution states "before" and "after" the transition.
   Contain at least a memory state (see later) and a way to tell the current control point.
- t trace of observable events performed during the transition, e.g. system calls and volatile memory accesses.
   The trace is empty for internal transitions.

### Generic shape of small-step semantics

```
Record semantics : Type := Semantics_gen {
   state: Type;
   genvtype: Type;
   step : genvtype -> state -> trace -> state -> Prop;
   initial_state: state -> Prop;
   final_state: state -> int -> Prop;
   globalenv: genvtype;
   symbolenv: Senv.t
}.
```

See module Smallstep for generic definitions and theorems about those semantics.

#### The Asm semantics

States: memory state  $\times$  register state (register  $\mapsto$  value).

One transition = execute the instruction pointed by register PC.

Broadly similar to the instruction set manuals of the target architecture and to processor formalizations such as [FM10, KBJD13].

More abstract in some respects:

- The code is immutable and not stored in memory.
- No bit-level encoding of instructions.

addx addx

Add (x'7C00 0214')

add	rD,rA,rB	(OE = 0 Rc = 0)
add.	rD,rA,rB	(OE = 0 Rc = 1)
addo	rD,rA,rB	(OE = 1 Rc = 0)
addo.	rD,rA,rB	(OE = 1 Rc = 1)

$$rD \leftarrow (rA) + (rB)$$

The sum  $(\mathbf{r}A) + (\mathbf{r}B)$  is placed into  $\mathbf{r}D$ .

The add instruction is preferred for addition because it sets few status bits.

Other registers altered:

• Condition Register (CR0 field):

NOTE: CR0 field may not reflect the infinitely precise result if overflow occurs (see next bullet item

· XER:

Affected: SO, OV (If 
$$OE = 1$$
)

NOTE: For more information on condition codes see Section 2.1.3, "Condition Register," and Section 2.1.5, "XER Register."

173 / 226

#### The Asm semantics

For most instructions there are no observable events (trace is empty) and the state after is a partial function Asm.exec\_instr of the state before.

Execution of builtin functions (e.g. volatile memory accesses) and external functions (e.g. system calls) can produce observables and use a language-independent semantics partially defined, partially axiomatized in module Events.

#### The RTL semantics

Execution states have more components and more structure:

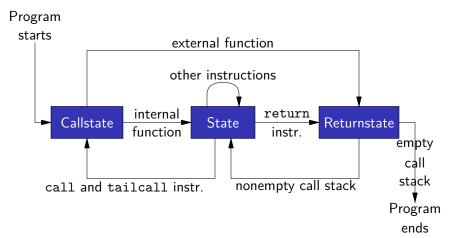

- f: RTL function currently executing
- sp: pointer to its stack frame
- pc: node of the CFG to be executed next
- rs: maps temporaries (pseudoregisters) to their values
- m: memory state
- stk: call stack (list of pending function calls, with f, sp, pc and rs)

175 / 226

Most transitions execute the instruction at node pc of the CFG of the current function f.

#### Handling of function calls and returns

Function calls and function returns are slightly different and use special intermediate states Callstate and Returnstate.

## The Clight semantics

Like in IMP, execution points are pairs (s, k) of a statement under focus s and a continuation k.

The continuation k also encodes the call stack (pending function calls).

Two local environments:

- *le*: name of temporary → current value

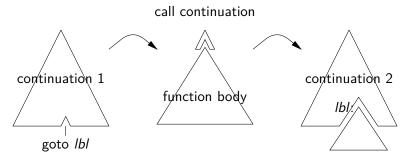

Like in IMP, expressions are evaluated in big-step style. Complications: overloading of operators; Ivalues and rvalues.

The semantics is parameterized and instantiated twice to give:

- Clight1 semantics: function parameters are addressable local variables
- Clight2 semantics: function parameters are temporaries.

## Handling goto by continuation surgery

A search function find\_label that finds a statement labeled *lbl* while manufacturing the corresponding continuation:

Implements the transition goto  $lbl/k_1 \rightarrow lbl: c/k_2$ .

### The CompCert C semantics

The semantics of statements is similar to that of Clight, using focusing and continuations.

Expressions can contain function calls

 $\Rightarrow$  small-step evaluation of expressions

Several evaluation orders are allowed for expressions

- ⇒ non-determinism
- ⇒ reductions under a context (Felleisen-style).

A reference interpreter (ccomp -interp) is provided to explore the semantics.

## Evaluation orders in C expressions

```
int a(void) { printf("a"); return 1; }
int b(void) { printf("b"); return 2; }
int c(void) { printf("c"); return 3; }
int main(void) { return a() + b() + c(); }
```

The subexpressions a() and b() and c() can be evaluated in any order that the compiler chooses.

 $\Rightarrow$  any of the 6 permutations abc, acb, bac, bca, cab, cba is a valid output for this program.

(This is different from saying that  $e_1 + e_2$  either evaluates  $e_1$  fully then  $e_2$ , or  $e_2$  then  $e_1$ , as in Scheme or OCaml.)

(The ISO C standards have a notion of *sequence points* that declare as illegal some expressions where different evaluation orders give different results. Function calls as in the above are not illegal.)

#### Reductions under contexts

(Felleisen and Hieb, 1989; Wright and Felleisen, 1992)

One or several head reduction rules, e.g. for the call-by-value  $\lambda$ -calculus,

$$(\lambda x.a) \ v \stackrel{\epsilon}{\to} a\{x \leftarrow v\}$$
  $(\beta_v)$ 

A single reduction under context rule:

$$\frac{a \stackrel{\epsilon}{\to} b}{\Gamma[a] \to \Gamma[b]}$$

A definition of valid reduction contexts  $\Gamma$ , often as a grammar:

Left-to-right evaluation:  $\Gamma$  ::=  $[] | \Gamma b | v \Gamma$ Right-to-left evaluation:  $\Gamma$  ::=  $[] | \Gamma v | a \Gamma$ Nondeterministic evaluation:  $\Gamma$  ::=  $[] | \Gamma b | a \Gamma$ 

#### Nondeterminism and going-wrong behaviors

Depending on evaluation order, an expression can evaluate normally, or diverge, or go wrong:

$$(x = 0) + (x = 1) + (10 / x)$$
  
 $loop() + (10 / 0)$ 

(Assuming loop is a function that never returns.)

Common sense and the ISO C standard say that an expression is undefined as soon as one evaluation order goes wrong. ("Demonic nondeterminism".)

The usual convention for head reduction rules is "no reduction if going wrong", as opposed to "reduce to ERROR if going wrong". To get demonic nondeterminism, we need one "reduce to ERROR" rule:

a is not a value and doesn't head-reduce

$$\Gamma[a] \to \text{ERROR}$$

### Quick tour of the Coq specification

Module Csem: the nondeterministic semantics.

- Head reductions: callred for function calls, rred for other r-value expressions, lred for l-value expressions.
- Contexts: functions  $C: \exp r \to \exp r$  constrained by the predicate context  $k_1$   $k_2$  C, where  $k_1$  is the kind (I-value or r-value) of the hole and  $k_2$  the kind of the result.
- Reduction of expressions: relation estep between states.
- Other transitions between states: relation sstep.

Module Cstrategy: the deterministic evaluation strategy implemented by CompCert. (Roughly: evaluate effectful subexpressions first, then finish.)

- Big-step evaluation of simple, pure subexpressions.
- Reductions under contexts for other expressions.
- Contexts (predicate lcontext) impose strict left-to-right evaluation.
- Reuses the sstep transitions of Csem.

# Compiler verification in the large: CompCert

- The CompCert project
- Tower of Babel: the languages of CompCert
- The CompCert memory model
- 14 Observables, non-determinism, and semantic preservation
- 15 Concluding remarks

### What is a memory model?

Semantics for imperative languages are expressed in terms of evolution of the state.

#### A memory model defines:

- What a state contains.
- The basic operations over states: at least read and write; also alloc and free.
- The properties of these operations
  - ⇒ reasoning over programs
  - $\Rightarrow$  reasoning over program transformations.

Not treated here: issues of weak consistency in the presence of parallelism with shared memory (threads).

### High-level memory models

#### For IMP:

a memory state = a mapping from variable names to values.

#### For Java, OCaml, etc:

a memory state = a mapping from abstract references to values.

(References are identifiers, like variable names; fresh references are created at dynamic allocation points.)

In both cases: the good variables properties:

load(store
$$(m, r, v), r$$
) =  $v$   
load(store $(m, r, v), r'$ ) = load $(m, r')$  if  $r \neq r'$ 

#### High-level memory models

For (a well-behaved fragment of) C and C++, we can use references to designate objects and paths to designate their sub-objects (record fields, array elements) [RF95]:

```
Path: p := r reference to top-level object \mid p. \text{field} \mid p \text{field} access to a field of a struct or union \mid p[i] \mid access to the i\text{-th} element of an array
```

The good variables properties become:

$$load(store(m, p, v), p) = v$$
  
 $load(store(m, p, v), p') = load(m, p') if p and p' are disjoint$ 

### Problems with low-level C programming idioms

High-level models have difficulties accounting for low-level C programming idioms such as byte-per-byte access to the representation of data:

```
void memcpy(void * dst, void * src, int n)
{
   int i;
   for (i = 0; i < n; i++) ((char *)dst)[i] = ((char *)src)[i];
}
double a[10], b[10];
memcpy(a, b, 10 * sizeof(double));</pre>
```

## Problems with low-level C programming idioms

Another low-level idiom that works only with IEEE floating-point numbers and a little-endian processor:

```
double copysign(double x, double y)
{
  union { double d, uint64_t i } ux, uy;
  ux.d = x; uy.d = y;
  ux.i &= 0x7FFFFFFFFFFFF;
  ux.i |= (uy.i & 0x80000000000000);
  return ux.d;
}
```

(This is not standard-conformant C but widely used in the field.)

#### Low-level memory models

A machine-oriented view of memory as a flat array of bytes [TKN07]

- Memory state = mapping  $int \mapsto byte$
- Pointer value = machine integer.

For each data type au of the language, define two functions

```
	ext{encode}_{	au} \; : \; 	au 	o 	ext{list byte}
```

 $\mathtt{decode}_ au$  : list byte o au

such that (at least)

$$decode_{\tau}(encode_{\tau}(x)) = x$$
  
 $length(encode_{\tau}(x)) = sizeof(\tau)$ 

#### Low-level memory models

Definition of memory operations:

$$\operatorname{load}_{\tau}(m, a) = \operatorname{decode}_{\tau}(m[a], \dots, m[a + \operatorname{sizeof}(\tau) - 1])$$
  
 $\operatorname{store}_{\tau}(m, a, x) = m[a, \dots, a + \operatorname{sizeof}(\tau) - 1 \leftarrow \operatorname{encode}_{\tau}(x)]$ 

Weak "good variables" properties:

$$egin{array}{lll} {
m load}_{ au}({
m store}_{ au}(m,a,x),a) &=& x \ {
m load}_{ au'}({
m store}_{ au}(m,a,x),a') &=& {
m load}_{ au'}(m,a') \ & {
m if} \ a'+{
m sizeof}( au') \leq a \ {
m or} \ a+{
m sizeof}( au) \leq a' \end{array}$$

#### Low-level memory models

#### Also need to account for:

- Alignment constraints, e.g. "for a 32-bit memory access, the address must be a multiple of 4".
  - $\Rightarrow$  define the minimal alignment of a type  $\mathtt{alignof}( au)$
  - $\Rightarrow$  enforce (alignof( $\tau$ ) | a) for a  $\tau$  access at a.
- Permissions / access rights. Some addresses do not correspond to working memory. Others correspond to readonly memory.
  - $\Rightarrow$  memory states include a mapping address  $\rightarrow$  permission

The CompCert permissions:

 ${\tt Empty} < {\tt Nonempty} < {\tt Readable} < {\tt Writable} < {\tt Freeable}.$ 

### The good, the bad, and the ugly

Good: all low-level C programming idioms can be accounted for.

**Bad:** C programs can observe too many things about memory:

Adjacency of data in memory:

```
int a[2], b[2]; a[3] = 42; return b[1]; // returns 42
```

• Relative order of data in memory:

```
int a, b; return &a < &b;</pre>
```

Absolute addresses:

```
int a; return &a == (int *) 4;
```

## The good, the bad, and the ugly

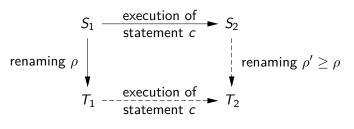

**Ugly:** program transformations in general and compilers in particular do not preserve these extra observations:

```
• Insertion of padding ⇒ invalidates adjacency properties
    int a[2], b[2]; a[3] = 42; return b[1];
-->
    int a[2], padding[2], b[2]; a[3] = 42; return b[1];
```

- Permutation of allocations ⇒ invalidates adjacency and relative order
   int a, b; return &a < &b; // returns true
  -->
   int b, a; return &a < &b; // returns false</pre>
- Late (link-time or run-time) placement of data
   ⇒ invalidates absolute addresses.

#### A sanity condition on semantics

Semantics for imperative languages should be invariant under renaming of references/addresses

High-level models: OK. Low-level models: no.

# The CompCert memory model [LABS14]

#### A "medium-level" memory model:

- States are composed of memory blocks (similar to top-level objects in the abstract C/C++ view), disjoint by construction, designated by abstract references b.
- The contents of a memory block are accessed by byte offsets, with alignment constraints and per-byte permissions, just like in a low-level model.
- Pointer values are pairs  $(b, \delta)$  of a block identifier b and a byte offset  $\delta$  (unsigned 32 or 64-bit integer, depending on the target processor).

Used for all the languages of CompCert, from C to Asm.

#### The CompCert value model

(Module Values)

Values are either pointers or numbers (different kinds), plus a special Vundef value meaning "an unknown bit pattern".

```
Inductive val: Type :=
   | Vundef: val
   | Vint: int -> val
   | Vlong: int64 -> val
   | Vfloat: float -> val
   | Vsingle: float32 -> val
   | Vptr: block -> ptrofs -> val.
```

#### In-memory encoding of values

(Module Memdata)

```
Inductive memval: Type :=
    | Undef: memval
    | Byte: byte -> memval
    | Fragment: val -> quantity -> nat -> memval.
```

#### The concrete encoding:

As a list of bytes (8-bit integers). Used for numbers (integers and FP).

Exposes bit-level representation (2's complement, IEEE754 FP) and processor endianness.

#### The abstract encoding:

As a list of symbolic fragments "the n-th byte of value v". Used for pointers.

# Main properties of the model

(Module Memory; see also [LABS14])

Weak good variables properties:

$$\operatorname{load}_{\tau}(\operatorname{store}_{\tau}(m,p,x),p) = x$$
  
 $\operatorname{load}_{\tau'}(\operatorname{store}_{\tau}(m,p,x),p') = \operatorname{load}_{\tau'}(m,p')$   
if  $p,p'$  point to different blocks  
or to disjoint areas of the same block

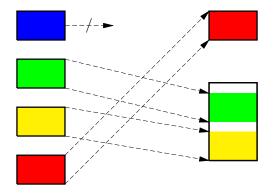

- Pointer values cannot be forged: the only way for a load to return a pointer value is for this pointer value to have been stored earlier at the same address.
- Compatibility with renamings of block identifiers.
- Compatibility with generalized renamings: memory injections.

## Memory injections

```
j: block \rightarrow option(block \times Z)

j(b) = \text{None}: block b disappears (e.g. contents pulled into a register)

j(b) = \text{Some}(b', \delta): block b becomes a sub-block of b' at offset \delta.
```

### Memory injections

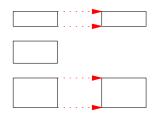

A memory injection j: block  $\rightarrow$  option(block  $\times$  Z) induces a correspondence  $j \vdash v \approx v'$  between values:

$$j \vdash \mathtt{Vundef} pprox \qquad \qquad j \vdash \mathtt{Vint}(i) pprox \mathtt{Vint}(i) \ \ \, rac{j(b) = \mathtt{Some}(b', \delta) \qquad o' = o + \delta \ (\mathsf{mod} \ 2^{\mathit{wordsize}})}{j \vdash \mathtt{Vptr}(b, o) pprox \mathtt{Vptr}(b', o')}$$

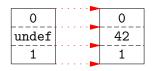

It also induces a correspondence between memory states  $j \vdash M \approx M'$ :

- No overlap between block images
- Block contents match.

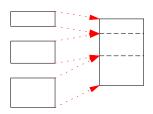

# Uses of memory injections in CompCert's proofs

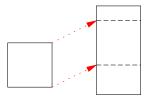

Pulling data out of memory (Clight1 to Clight2)

Refinement of stored values (many passes)

 $\begin{array}{c} \text{Merging blocks} \\ \text{(C\#minor to Cminor; inlining)} \end{array}$ 

Extending stack frames (spilling)

# Compiler verification in the large: CompCert

- The CompCert project
- 12 Tower of Babel: the languages of CompCert
- The CompCert memory model
- 14 Observables, non-determinism, and semantic preservation
- Concluding remarks

#### Semantic preservation in early CompCert

The first versions of CompCert were similar to big-step IMP, in that:

- The semantics only let us observe termination with a given exit status (return value of the main function).
- The semantic preservation result proved was of the form
   If the source Cminor program terminates with status N,
   the generated assembly code also terminates with status N.
- The assembly language had deterministic semantics, hence no other behavior of the compiled code was possible.

# The need for stronger preservation properties

Most real programs produce more output than just an integer exit status, e.g. write results to files.

Many real programs are interactive and input data in addition to outputting it.

Many real programs are intended to run forever; termination is an error. This is the case of servers but also of control-command codes.

```
every \delta t seconds do acquire \mathit{current-state} from sensors compute \mathit{action} = \mathit{control-law} (\mathit{desired-state} - \mathit{current-state}) send \mathit{action} to \mathit{actuators} done
```

#### Observing more behaviors

- 1- Associate observable events to certain actions of the program:
  - Calls to the OS or to a standard I/O library,
     e.g. putchar, getchar.
  - Reads from and writes to volatile global variables, because these variables can correspond to hardware I/O devices.
- 2- Describe diverging (non-terminating) executions in addition to terminating executions.

## Labeled Transition Systems

$$genv \vdash state_1 \xrightarrow{t} state_2$$

Classically, labels t are either  $\tau$  (for internal, non-observable computations), c!v for output operations, and c?v for input operations.

In CompCert, t is a list of observable events (see module Events). The list is empty for internal computations.

Events come in several kinds and can combine output and input, e.g. "call system function F with argument out and get result in".

#### From transitions to whole-program behaviors

Normal termination with trace  $a_1 \dots a_k$ :

$$\mathtt{initial}\ni s\stackrel{\tau}{\to} s_1\stackrel{\mathsf{a_1}}{\to} s_2\stackrel{\tau}{\to}\cdots\stackrel{\mathsf{a_k}}{\to} s_n\in\mathsf{final}$$

"Going wrong" with trace  $a_1 \dots a_k$ :

$$\texttt{initial} \ni s \xrightarrow{\tau} s_1 \xrightarrow{a_1} s_2 \xrightarrow{\tau} \cdots \xrightarrow{a_k} s_n \in \mathsf{error}$$

Reactive divergence with infinite trace  $a_1 \dots a_k \dots$ :

$$\texttt{initial} \ni s \xrightarrow{\tau} \cdots \xrightarrow{a_i} \xrightarrow{\tau} \xrightarrow{\tau} \xrightarrow{\tau} \cdots \xrightarrow{a_j} \xrightarrow{\tau} \xrightarrow{\tau} \cdots$$

Silent divergence with trace  $a_1 \dots a_k$ :

$$\texttt{initial} \ni s \xrightarrow{\tau} \cdots \xrightarrow{a_k} s_n \xrightarrow{\tau} \xrightarrow{\tau} \xrightarrow{\tau} \xrightarrow{\tau} \cdots$$

#### Simulations

Using these notions of whole-program behaviors, we can reuse the framework from part 2 of this lecture to define forward simulation and backward simulation between an original program  $P_1$  and a compiled program  $P_2$ :

#### Backward simulation with improvement:

Any observable behavior  $b_2$  of  $P_2$  is identical to or improves upon a possible behavior  $b_1$  of  $P_1$ .

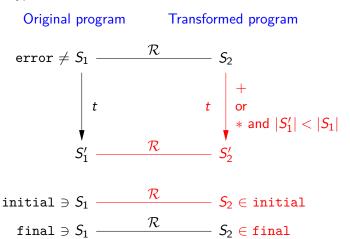

#### Forward simulation with improvement:

Any possible behavior  $b_1$  of  $P_1$  is identical to or is improved by a possible behavior  $b_2$  of  $P_2$ .

However, these simulations can be defined directly in terms of the labeled transition systems for  $P_1$  and  $P_2$ , as commutative diagrams.

#### Forward simulation diagram

 $\mathcal{R}$  is a relation between execution states of the two programs. Black = hypothesis; red = conclusion.

# Early CompCert semantic preservation proofs (See [Ler09b])

- Show safe forward simulation for every compilation pass.
   (Using simulation diagrams and small-step semantics, mostly.)
- Show safe forward simulation for the whole compiler by composing the per-pass simulations.
- 3 Argue that the target language (Asm) is deterministic.
- Onclude that we have safe backward simulation.

#### Issues with external nondeterminism

Input operations ("c?v" events in the trace) receive values v that are not determined by the program, but instead chosen by the environment.

For example, reading from a global volatile variable returns any value of its type.

Hence the Asm semantics is not deterministic:

Workaround: determinize the environment by making input values partial functions of an initial environment state and of the previous outputs of the program.

#### Issues with internal nondeterminism

A compiler pass that reduces internal nondeterminism (e.g. by selecting one evaluation order among several permitted orders) cannot enjoy a forward simulation property.

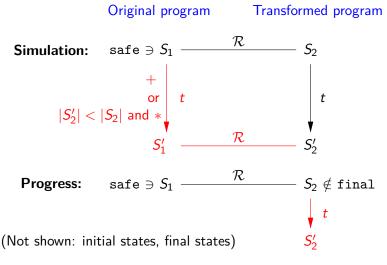

(Forward simulation: every behavior of the source is matched by a behavior of the compiled.)

Early CompCert: problem not apparent because the  $C \rightarrow Clight$  pass that chooses an evaluation order was not formally verified yet.

Later CompCert: use a backward simulation diagram to relate

- CompCert C with multiple evaluation orders
- CompCert C with the fixed order from module Cstrategy then a forward simulation from the latter to Clight.

## Backward simulation diagrams

 $S \in \mathtt{safe}$  means  $\neg$   $S \xrightarrow[\tau]{*} \mathtt{error}$  (cannot crash silently).

X. Leroy (Inria) Compiler verification DSSS 2017 214 / 226

## From determinism to determinacy and receptiveness

In their CompCertTSO work [SVN $^+$ 11], Sevcík, Vafeiadis, Zappa Nardelli, Jagannathan and Sewell show how to get rid of the "deterministic external world" hypothesis, by reasoning purely over diagrams and forgetting about whole-program behaviors.

#### Theorem (Sevcík et al)

Assume a forward simulation diagram from LTS  $L_1$  to LTS  $L_2$ . If  $L_1$  is receptive and  $L_2$  is determinate, there exists a backward simulation diagram from  $L_1$  to  $L_2$ .

Proof: highly nontrivial; see module Smallstep.

## Determinacy and receptiveness

Two labels are compatible  $\ell_1 \simeq \ell_2$  if they differ only by input values. (i.e.  $\ell_1 = \ell_2 = \tau$  or  $\ell_1 = \ell_2 = c!v$  or  $\ell_1 = c?v_1, \ell_2 = c?v_2$ .)

A language is determinate if:

- $s \stackrel{\ell_1}{\to} s_1$  and  $s \stackrel{\ell_2}{\to} s_2$  imply  $\ell_1 \asymp \ell_2$ .
- $s \stackrel{\ell}{\to} s_1$  and  $s \stackrel{\ell}{\to} s_2$  imply  $s_1 = s_2$ .

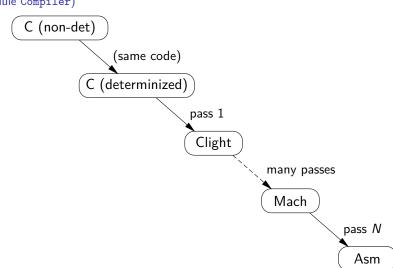

In other words: the only nondeterminism comes from the input values in labels. This is the case for Asm and all other CompCert language except CompCert C (because of its internal nondeterminism).

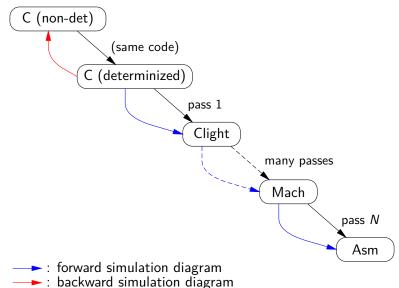

A language is receptive if:

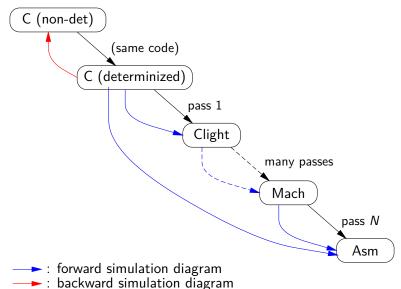

•  $s \stackrel{\ell_1}{\to} s_1$  and  $\ell_1 \asymp \ell_2$  implies  $\exists s_2, s \stackrel{\ell_2}{\to} s_2$ .

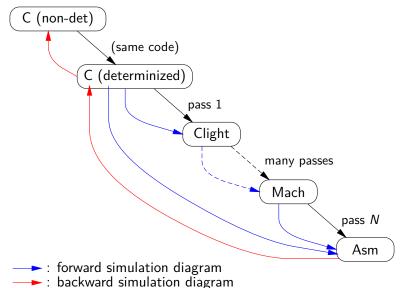

In other words: a transition with an input is possible regardless of the value of the input. This is the case for all CompCert languages.

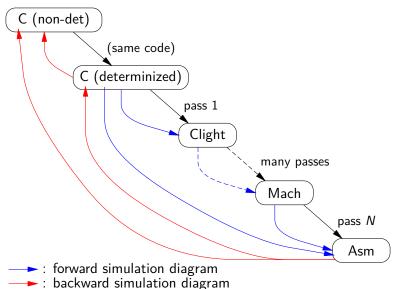

## Putting it all together (Module Compiler)

## Compiler verification in the large: CompCert

- The CompCert project
- 12 Tower of Babel: the languages of CompCert
- 13 The CompCert memory model
- (4) Observables, non-determinism, and semantic preservation
- 15 Concluding remarks

#### On tool verification

CompCert is still an ongoing project, but it demonstrates that the formal verification of realistic compilers is feasible (within the limitations of today's proof assistants).

Some related tool verification projects:

- CakeML (compiler for core ML)
- Velus (Lustre→C code generator)
- Verasco (C static analyzer based on abstract interpretation)
- The Verified Software Toolchain at Princeton

## Future directions for CompCert

- Increase confidence further by reducing the number of unverified components.
- Re-engineer and model differently to be more easily extensible, e.g. to new target processors and ABIs.
- Add more optimizations, esp. loop optimizations.
- Extend the verification "up" to connect with more abstract semantics of C such as Krebbers's [Kre15].
- Extend the verification "down" towards instruction set architectures (machine language, e.g. [FM10, KBJD13]) and hardware implementations (e.g. the CLI stack [Moo96]).
- Support shared-memory concurrency.
   Early attempt: CompCertTSO [SVN+11]. Ongoing work at Princeton.

### On trusting the specifications

A difficult problem, faced by all kinds of formal verifications.

A small simplification in the specifications is worth a large increase in proof effort.

In the DeepSpec project: exercise specifications by connecting them to multiple verifications.

Executable specifications (e.g. reference interpreters) can also help:

- For testing the specifications.
- To discuss with standard committees.

#### On mechanized semantics

A need shared by many verification efforts, not just verified compilers.

A difficult task, especially for realistic programming languages (i.e. Java and the JVM; C; Javascript; C++).

Machine assistance is a necessity to scale up to realistic programming languages.

The sensitivity is disturbingly high: adding one language feature can deeply impact the whole semantics.

The unreasonable effectiveness of Labeled Transition Systems (despite looking more like abstract machines than high-level specs).
